SECONDARY STRESSES IN BRIDGES*

By Cecil Vivian von Abo,† Jun. Am. Soc. C. E.

With Discussion by Messrs. O. H. Ammann, William Cain, Almon H. Fuller, K. P. Bahjejian, C. A. P. Turner, P. L. Pratley, Henry S. Jacoby, Charles Evan Fowler, H. M. MacKay, George E. Beggs, D. B. Steinman, Thomas C. Shedd, Hardy Cross, W. M. Wilson, Thomson E. Mao, Edward Godfrey, Cyrus C. Fishburn, F. P. Shearwood, Laurence J. Waller, R. McC. Beanfield, and Cecil Vivian von Abo.

Synopsis

The paper first describes all the methods which have been proposed for the complete analysis of secondary stresses due to the rigidity of the joints in bridge trusses. Approximate methods, however, such as those of Engesser and Landsberg, which neglect the effect of the web system, are not included.

A typical through railway bridge of six panels is analyzed by each method in turn, using unsymmetrical loading, in order to test more thoroughly the advantages and disadvantages of each method. A critical comparison is then made of the methods thus applied.

Influence lines are developed for the secondary stresses in all the members of the main trusses, in the top chords as effected by the top lateral system, and in a typical cross-frame. These influence lines are then combined for the purpose of computing the maximum secondary stresses in certain typical members.

PART I

1.—Introduction

Prior to 1879, no form of mathematical analysis was known, and no empirical results were available, which would enable an engineer to calculate

* Presented at the meeting of November 5, 1924. This paper was presented by Mr. von Abo in September, 1922, as a thesis to the Committee on Graduate Studies of McGill University for the degree of Doctor of Philosophy.

† Care, Chf. Civ. Engr., South African Rivers and Harbors, Johannesburg, Transvaal, South Africa.

with reasonable accuracy the stresses in a structure as built. Even after that date, when Manderla gave his excellent solution of secondary stresses due to the restraint of members meeting at a joint, little attention was paid to such stresses for many years. The labor involved in the calculations was usually the reason given for this neglect; but it is possible that lack of familiarity with the subject played an equally important part.

In recent years the construction of such phenomenal bridges as the Quebec cantilever, the Sciotoville continuous truss, and the Hell Gate arch, has awakened new interest in the subject. The Engineering Profession owes much to those in charge of these structures for the accounts of their investigations. Of particular interest is the paper by D. B. Steinman, M. Am. Soc. C. E., on "Stress Measurements on the Hell Gate Arch Bridge" (33),* with the full discussion by leading bridge engineers.

In recent specifications the tendency is to recognize the importance of secondary stresses. Higher unit stresses are properly permitted for combinations of secondary and primary stresses. This undoubtedly leads to a better distribution of metal, and to a more uniform strength throughout the structure. Although many think that the calculation of secondary stresses in ordinary spans will seldom be necessary, the writer believes that if the Engineering Profession at large becomes thoroughly versed in the matter, the strength and economy of all bridges will be superior to any that may be built with what has been so appropriately called "the factor of ignorance".

Definition of Secondary Stresses.—The most general definition of "secondary stress" would include shearing and torsional stresses. For the purposes of this paper, however, these are not considered, but rather the direct stresses, tensile or compressive, of the fibers parallel to the center line of a member. This member, under loading, transmits a certain total stress, which, if divided by the area of cross-section, gives an average unit stress; this is the uniform unit stress in the member of the ideal bridge. If, however, in the actual case, some particular fiber be considered and it were possible to determine its elongation, and, therefore, its unit stress, in general this unit stress would differ from the average. Therefore, at any particular cross-section of a member in a bridge, the amount by which the unit stress in any longitudinal fiber differs from the average unit stress, found by dividing the total direct stress by the area, is called the secondary stress of that fiber.

This paper is concerned with the maximum variation, at the four edges of the member, as far away from the center line as possible, for it is there that stresses are most severe.

Classification.—In 1914 a committee of the American Railway Engineering Association classified the secondary stresses in bridges.† The writer, however, suggests the following classification:

(1) Secondary stresses, arising from rigid or partly rigid connections.
(2) Secondary stresses, arising from the beam action of members.
(3) Secondary stresses developed in axially loaded members.
(4) Secondary stresses due to faulty design.

* Figures in parentheses refer to numbered articles in the Bibliography.
† *Proceedings*, Am. Ry. Eng. Assoc., Vol. 15 (1914).

Class (1) would take care of any secondary stresses that may arise in the various plane frames due to the rigidity of the joints in those planes. The bridge trusses, the top lateral system, the floor system, and the various cross-frames would contribute to this class. Imagine a bridge to be in equilibrium under a stationary train load. Certain secondary stresses will be found in each of the trusses. The top chords of both trusses change in length, while the other top lateral members remain constant in length; hence, secondary stresses are found in the top lateral system. In the same way, the changes in length of the bottom chords, with no changes in length of the floor-beams and stringers, introduce secondary stresses in the floor system. Finally, in the cross-frames the floor-beams bend under loads in the adjoining panels; if these floor-beams were pin-connected to the two trusses, the bending stresses in the floor-beams would be simply those of Class (2), but, as the floor-beams are rigid parts of the cross-frames, secondary stresses exist in the frames as a whole, which should be regarded, therefore, as in Class (1).

Imagine that a gale is blowing. It has the effect of changing this arrangement, which is symmetrical about the vertical plane dividing the bridge in half along its length, making it unsymmetrical, while certain direct stresses induced by the wind in the top lateral and the floor systems superimpose secondary stresses on the ones already found. In the case of a wind, too, the end portals come into play and are placed in Class (1).

Class (2) needs little explanation, for a member has bending stresses developed by its own weight and by any wind pressure against it.

Class (3) is seldom, if ever, reckoned as part of a study of secondary stresses. In leading up to the definition of secondary stresses, the assumption was made that the compression members in the ideal bridge were to behave just opposite to those in tension. Euler showed, however, that a column does not transmit a uniform compression under an axial load. Since then many investigators have striven after solutions of this problem, which is all the more complex when the column is a built-up one with diaphragms, latticing, etc. It must be remembered that this member suffers bending under transverse loads, such as dead weight or wind; any axial load, which may now be regarded as an eccentric load, induces further bending stresses.

Mathematical analysis, supported by practical investigation, shows that, in the case of eye-bars transmitting an axial load, the fibers across the section through the center of the pin do not suffer uniform deformation. In fact, the unit stress of the fibers on the circumference of the hole is three times the average stress across the section. This property of an eye-bar is, therefore, a cause of secondary stresses.

Under Class (4) appear eccentric connections. A careful set of measurements would indicate the values of these eccentricities fairly accurately, in which case they could be judiciously incorporated in analyses of Class (1). There is in this class, however, a condition which defies the engineer, such as occurs, for example, when a compression member is made up of two channels which are supposed to have the same cross-section and to share the load equally. Generally, such an equal distribution is not found. This, of course, would

cause a variation in the secondary stress from that found by assuming the load to be shared equally.

The Superposition Theory, Applied to Secondary Stress Analysis.—In analyzing for the primary stresses in a structure, that is, regarding it as ideal and the stresses as pure tensions or pure compressions, it is possible to solve the problem in three dimensions, but it is far easier to regard the structure as being made up of a number of planes, solving for the stresses in each plane produced by forces that act in that plane, and simply adding algebraically the stresses for all the planes of which the member forms a part. This is the superposition theorem—the method of analysis commonly used by engineers.

In analyzing for secondary stresses, the only known method is to solve in a plane structure; even if it were possible to solve for secondary stresses in a space frame, the case of the primary stresses is conclusive evidence that the corresponding secondary stress problem will be most complicated and laborious.

Suppose for the moment that, by some method or other, the secondary stresses have been determined in the members belonging to one of the plane frameworks, for instance, one of the trusses, due to a certain loading in that plane. The so-called neutral axes of the members are really neutral planes. These planes pass through the centers of gravity of the members and are perpendicular to the plane of the truss. The fibers, the secondary stresses of which presumably have been found, are those lying along the planes on both sides of, parallel to, and farthest remote from, the neutral planes.

This same loading also induces secondary stresses in the top lateral system, but in this case the plane is horizontal, and the neutral planes are vertical. (This assumes that the top chords are straight, but the argument applies to the case where the top chords are curved or made up of a number of straight parts.) The top chords of the trusses are also parts of this new plane. In the former case, the neutral planes were planes perpendicular to the vertical truss plane; in the latter, the neutral planes are perpendicular to the horizontal top lateral plane. Whereas the secondary stresses of the top chord, as part of the truss, were for the fibers that lie along its top and bottom sides, the secondary stresses of the top chord, as part of the top lateral system, are for the vertical sides. The four corner fibers are affected in both analyses and, in order to obtain the greatest variations from the average stress, it is necessary to compound the secondary stresses in the two cases. This overlapping effect should be kept in mind throughout the analysis of a bridge, in order to arrive at a true estimate of the secondary stresses.

Another Definition of Secondary Stress.—A good practical definition of these stresses is as follows:

"The secondary stress in any member at any section is equal to one-half the difference between the two extreme fiber stresses measured at the same section; the primary stress is then equal to one-half the sum of the same extreme fiber stresses."

This is the case where the member is part of a single plane framework—no other planes influence it. The two extreme fiber stresses are those belonging to the two sets of fibers on opposite sides of the neutral plane. This definition is justified only if all the stresses are within the elastic limit and if Bernoulli's

assumption holds. Let $ABCD$ (Fig. 1), be any cross-section of the member; the definition is true if the fibers on one side of the neutral plane, XX, and at equal distances from it are stressed equally. That is, ab represents the stress in every longitudinal fiber passing through AB, and cd represents the stress in every longitudinal fiber passing through CD.

Therefore, the cross-section, $ABCD$, may be replaced by any line parallel to AD and BC, and the problem regarded as an investigation of the stresses along this line. Hence the secondary stress is $\frac{1}{2}(ab - cd)$ and the primary stress $\frac{1}{2}(ab + cd)$.

It is somewhat different in practice, however. Following the assumption of Bernoulli, the diagram will be shown in Fig. 2. The trapezoid, $abb'a'$, repre-

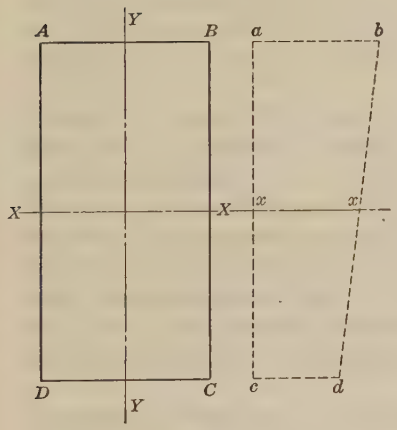

FIG. 1.

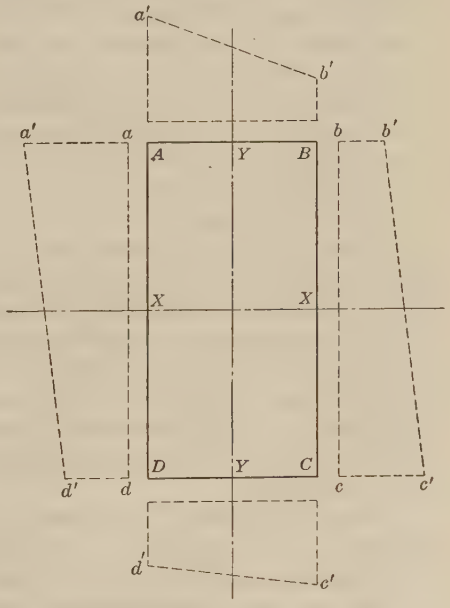

FIG. 2.

sents the stresses along the fibers that cross AB, $bb'c'c$ those along the fibers that cross BC, etc. In the case considered, $abb'a'$ and $cdd'c'$ were rectangles. Assuming that the variations along AB, BC, CD, and DA are uniform, it appears that, as the bb' of $abb'a'$ is the bb' of $bb'c'c$, etc., the primary stress is $\frac{1}{4}(aa' + bb' + cc' + dd')$, and the secondary stress at A is $\frac{1}{4}(aa' + bb' + cc' + dd') - aa'$, with similar expressions at B, C, and D.

This affords a more comprehensive definition:

"The primary stress is the average of the actual stresses found at the four corners of a member; the secondary stress is then the difference between this average and the actual stress of the fiber considered."

2.—Historical Notes

Derivation of Names.—The term "secondary stresses" is due to German writers, who classed all stresses in a bridge under (1) *Grundspannungen* (primary stresses), and (2) *Sekundarspannungen* (secondary stresses).

The *Grundspannungen* are themselves divided into (*a*) *Hauptspannungen* (principal stresses), and (*b*) *Zusatzspannungen* (additional stresses). The *Hauptspannungen* arise from the dead load and the live load, the latter being considered as a static load, while the *Zusatzspannungen* are due to wind pressure, traction, centrifugal force, and impact. The *Grundspannungen* are the stresses of the ideal structure, all pure tensions and pure compressions.

The fixedness of the joints, the weights of the members (distributed and not concentrated at the ends), the wind pressure acting in the same way, the property of axially loaded columns—all contribute to the distortion of the uniform stress distribution of the ideal case, the amount of distortion for a fiber being its *Sekundarspannung* (secondary stress).

Account of the Theoretical Investigations for Bridge Trusses.—In 1877, the Technical University of Munich offered a prize for the solution of a problem, worded by Professor Asimont as follows: What stresses arise in the members of a bridge truss owing to the fact that the angles of the truss triangles suffer no change?

In 1879, H. Manderla, an Assistant in the Technical University of Munich, submitted an excellent solution (3). His mathematical analysis is most exact, for the effects of the direct or primary stresses on the bending moments at the ends of members are taken into account. Hyperbolic functions are necessary for the solution of the differential equation, and infinite series are found in the expressions for the bending moments. As the solution of a problem by the exact method is laborious, and the values of the bending moments generally differ little from those found by a method in which the direct stress is not considered, it is this latter more approximate method that is generally known and always used.

Professor Engesser. of Karlsruhe, Germany, has published* a method in which he omitted the effect of the web system, the bending stresses of which are generally small compared with those in the heavy chord members.

The first detailed computations of secondary stresses are to be found in Part I of Winkler's "Theorie der Brücken", 1881 (4). In this painstaking work, the author gives methods for determining the magnitude of secondary stresses, as well as means of reducing them. He also points out the existence of secondary stresses in pin-connected trusses; Manderla confirmed this by extensometer measurements on the Waltenhofen Bridge.

In 1885, Professor Landsberg, of Hannover, Germany, gave an approximate graphical solution, based on the assumption that only the chords are riveted (5). This, like Engesser's method, neglects the web system. During the same year, Professor Müller-Breslau, of Berlin, Germany, contributed an analytical solution (6). In 1890, Professor W. Ritter, of Zurich, Switzerland, gave his graphical solution (7), and, in 1892, Professor O. Mohr presented his semi-

* *Zeitschrift für Baukunde*, 1879.

graphical one. In 1893, Professor Engesser published a thorough treatise on secondary stresses (8).

A remarkable work on secondary stresses was produced in 1902 by Professor E. Patton, of Moscow, Russia (10). His aim was to prove the great advantages of the double intersection trusses, then in common use in Russia. Professor Patton made a summary of the results obtained by computing the maximum primary and secondary stresses of five different bridge trusses, together with those obtained by other prominent scientists. These data enabled him to draw certain curves and study the relations between secondary stresses and the stiffness of the members. The Patton curves, however, give only a rough approximation, as the effect of the truss system and of the distribution of the loads on secondary stresses had not been taken into consideration.

It was not until 1905 that a written discussion in English appeared. In that year, Professor Isami Hiroi, of the Tokyo Imperial University, Tokyo, Japan, published his "Statically-Indeterminate Stresses in Frames Commonly Used for Bridges" (12). He uses the method of least work to find the secondary stresses in bridge trusses and also in the cross-frames. The method is long, and has no checks; therefore, it is not often used. The German periodical, *Der Eisenbau,* contains some remarkable treatises on the subject of secondary stresses, including a method of solving secondary stresses in various types of frames by Professor Mohr, of Dresden, Germany. He makes use of what is known as elastic weights, a method purely analytical (19).

A second method found in *Der Eisenbau* is due to Dr. Pirlet, of Aachen (20). He treats pairs of bending moments at the ends of adjacent members entering a joint as the unknown quantities; there are as many such pairs as there are angles in the truss, or 3 (n-2), in which n is the number of joints and (n-2) the number of triangles. He obtains equations that are of Gauss' normal type. His method is interesting and shows how closely the solutions of secondary stresses and of indeterminate stresses are related. The practical use, however, is small, as Manderla's method requires the solution of only n simultaneous equations of Gauss' normal type, and, therefore, is far superior to that of Pirlet.

Turneaure has developed invaluable methods of tabulating the various quantities, of solving the simultaneous equations, and especially of choosing the panel-point loads for influence lines (25).

In 1913, Mr. José Páez submitted a remarkably fine thesis to Cornell University, entitled "A Comparative and Critical Study of the Different Methods of Computing Secondary Stresses in Bridge Trusses" (27). In 1917, Dr. T. E. Mao also presented a thesis to Cornell University on the study of a large spandrel-braced arch (28); he made extensive use of Gauss' method to solve the equations leading up to the secondary stresses. Two years later, he presented a thesis on "Secondary Stresses" (34) to the Carnegie Institute of Technology, Pittsburgh, Pa., when he obtained the degree of Doctor of Engineering.

Practical Investigations for Bridge Trusses.—The foregoing is a brief account of the theoretical investigations of secondary stresses in bridge trusses

due to the rigidity of the joints. Turning to practice for verification, it is most gratifying to know that many investigations in the field have been made. Manderla was the first investigator; he experimented on the Waltenhofen Bridge. In 1883, Frankel made the first direct measurement of secondary stresses. In 1899, Mesnager published an account of the measurement of stresses in a Pratt truss of 180-ft. span on the Orleans Railway in France.* In 1901, M. Rabut described a series of stress measurements which had been made on a bridge of the Orleans Railway. During 1905 and 1906, W. Gehler conducted a series of tests on a railway bridge, of 128-ft. span, near Elsterwerda, Saxony. In addition to extensometers of the Frankel type, he used sensitive levers. A detailed report of the computations, experiments, and results is to be found in Professor Gehler's book (15). During 1907, 1908, and 1909, extensive secondary stress measurements were made by Professors Crandall and Turneaure, under the auspices of the American Railway Engineering Association. This investigation was primarily to determine the "additional" stress that had to be allowed for impact. A number of plate girders and truss bridges, ranging in span from 30 to 440 ft., were tested for both impact and secondary stresses, but in the latter case the investigations were performed only when the test load was traveling over the bridge at speeds that produced no impact.

In 1915, Mr. Steinman carried out extensive measurements on the Hell Gate Arch (33). Some results were found to conflict with theory, but on the whole the investigation is a remarkable verification of the theory. Recently, quite a number of investigations have been carried out in Switzerland and in England (36). The results of many investigations have not been published, and, therefore, are not available to the profession.

Cross-Frames.—Dr. Hiroi explains the method of solution of a cross-frame, using the principle of least work (12). Dr. Cyril Batho, of McGill University, has a neat way of applying the slope-deflection method in his own solution. Professor Mohr makes use of elastic weights, not only to solve problems of cross-frames, but also the Vierendeel truss, a type found in Europe, principally in Belgium; this is a truss that has no diagonals, but depends on the stiffness of the chords to transmit the shear.†

Column Action.—A history of secondary stress investigations must include an account of the investigations on columns. Such an account would practically mean a résumé of the theory of columns, but only two investigations will be mentioned. The treatise by H. M. Westergaard, Assoc. M. Am. Soc. C. E., on "Buckling of Elastic Structures"(35), not only throws much light on the subject but also has a useful bibliography. Perhaps the finest practical contribution was the series of investigations on columns and eyebars, carried out under the direction of H. M. MacKay, M. Am. Soc. C. E., of McGill University, in connection with the Quebec Cantilever Bridge.‡

PART II.—ANALYSIS OF SECONDARY STRESSES IN A BRIDGE TRUSS DUE TO THE RIGIDITY OF ITS JOINTS

1.—Manderla's Method

Introduction.—Consider the analysis of a truss made up of triangular elements. If quadrilaterals or other polygons are involved, as in the case of trusses with subdivided panels, the introduction of imaginary members, with zero cross-section and zero load, transforms such polygons into triangles. The assumption is that, if there are two trusses, identical except that one has riveted joints while the other has perfectly frictionless hinges, and if these trusses could be interchanged, the positions assumed by the joints of the riveted truss under a certain load and those by the corresponding joints of the hinged truss under the same load are identical.

When a truss with frictionless hinges is loaded every member suffers some definite elongation or contraction, and the positions of the joints change to agree with these deformations. The important facts to remember are that (1) all the members remain perfectly straight; (2) no bending stresses are introduced; (3) the angles of each triangular element are changed; and (4) the angles between adjacent members at a joint are likewise changed.

If the joints were fixed, and some means were used for forcing the members to positions where the angles at the joints again assume the values they had before loading, the members of the hinged truss would take up the exact positions and shape of the corresponding members in the riveted truss under the same load, for the effect of a gusset-plate at a joint is to keep the angle between any pair of members at the joint constant at all times. The problem, therefore, is to calculate the changes of angle between adjacent members of the hinged truss, and also the value of the bending moment at each end of every member necessary to make these changes zero.

Changes of Angle in a Triangular Element.—Knowing the unit axial stress in each member of a given triangular element, as well as the modulus of elasticity of the material, the angular changes may be computed by any one of several methods. The following is a neat graphical method due to Ritter. Let ABC (Fig. 3) be any triangular truss element and s_1, s_2, and s_3, the unit stress in the sides, BC, CA, and AB, respectively.

Draw a line through A perpendicular to the opposite side, BC, and cut off a length, AA', equal to s_1, the stress, BC. Through A' draw a line parallel to BC and terminated by the sides, BC, AB. Repeat this operation for the other two vertices.

For a change of length in the member, BC, the contributions toward the changes of angle will be found to be:

$$E \cdot \Delta \alpha_1 = +a$$
$$E \cdot \Delta \beta_1 = -a''$$
$$E \cdot \Delta \gamma_1 = -a',$$

for a change in the member, CA:

$$E \cdot \Delta \alpha_2 = -b'$$
$$E \cdot \Delta \beta_2 = +b$$
$$E \cdot \Delta \gamma_2 = -b'',$$

and, finally, for a change in the member, AB:

$$E \cdot \Delta \alpha_3 = -c''$$
$$E \cdot \Delta \beta_3 = -c'$$
$$E \cdot \Delta \gamma_3 = +c.$$

The total change, $\Delta \alpha$, of α due to a simultaneous change in length in all the members will be found by compounding the three contributions to α in the previous equations, namely:

$$\left.\begin{aligned} E \cdot \Delta \alpha &= E \cdot \Delta \alpha_1 + E \cdot \Delta \alpha_2 + E \cdot \Delta \alpha_3 \\ &= +a - b' - c'' \end{aligned}\right\} \quad \text{Similarly,}$$

$$\left.\begin{aligned} E \cdot \Delta \beta &= +b - c' - a'' \end{aligned}\right\} \quad \text{and,} \qquad \ldots\ldots\ldots\ldots(1)$$

$$\left.\begin{aligned} E \cdot \Delta \gamma &= +c - a' - b'' \end{aligned}\right\}$$

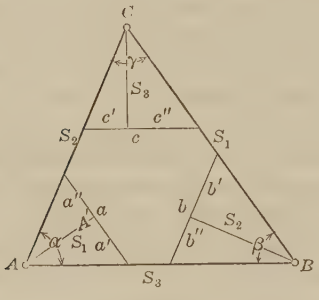

FIG. 3.

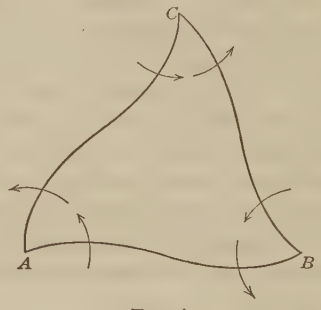

FIG. 4.

To make these results suitable for analytical computation it is to be noted that:

$a' = s_1 \cot \beta$	$b' = s_2 \cot \gamma$	$c' = s_3 \cot \alpha$
$a'' = s_1 \cot \gamma$	$b'' = s_2 \cot \alpha$	$c'' = s_3 \cot \beta$
$a = s_1 (\cot \beta + \cot \gamma)$	$b = s_2 (\cot \gamma + \cot \alpha)$	$c = s_3 (\cot \alpha + \cot \beta)$

Therefore, Equations (1) become:

$$\left.\begin{aligned} E \cdot \Delta \alpha &= (s_1 - s_2) \cot \gamma + (s_1 - s_3) \cot \beta \\ E \cdot \Delta \beta &= (s_2 - s_3) \cot \alpha + (s_2 - s_1) \cot \gamma \\ E \cdot \Delta \gamma &= (s_3 - s_1) \cot \beta + (s_3 - s_2) \cot \alpha \end{aligned}\right\} \qquad \ldots\ldots\ldots\ldots(2)$$

These are the fundamental equations for the changes of angle when the intensities of stress in the three sides are known. There are many ways of arriving at these equations, Manderla himself using the differential calculus. Because of the application to graphics in Ritter's method, and in that of Mao, and because the method mentioned is the easiest, it will be the only one reproduced.

Equations (2) are easily remembered. Fix attention on one angle of a triangle. The difference between the stresses in the opposite side and one of the adjacent sides is multiplied by the co-tangent of the included angle. Two such terms are found, their sum being the product of the required change in the angle considered and E, the modulus of elasticity.

Bending Moments Introduced at the Joints.—Consider the triangle, *ABC* (Fig. 4), representing the shape that the frame of Fig. 3 would assume if the members were forced round so that the angles at *A*, *B*, and *C* have the same value as before loading. Fig. 4 also represents the shape that the triangular framework of the riveted truss actually assumes under load. The member, *AB*, is represented by itself in Fig. 5.

Let the bending moments at *A* and *B* be M_1 and M_2, both counterclockwise. There must be shearing forces at *A* and *B*; let these be V_1 upward at *A* and V_2 downward at *B*. They are, of course, equal in magnitude, for *AB* is in equilibrium and V_1 and V_2 are the only two vertical forces.

Finally, there is some force, *P*, along *AB*—this is the total stress transmitted by the member and assumed to be tension in this case.

The moment at any point, *N*, at a distance, *x*, from *A* is:

$$M_x = M_1 - P \cdot y - V_1 \cdot x \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (3)$$

in which *y* is the offset of the center of gravity of Section *N* from *AB*.

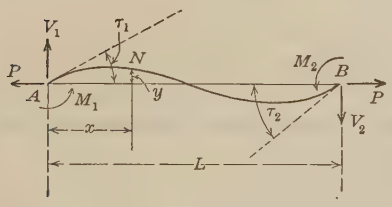

FIG. 5.

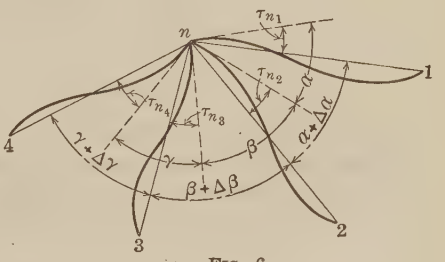

FIG. 6.

The differential equation of the elastic line is:

$$\frac{d^2 y}{d x^2} = -\frac{M_x}{E I} = -\frac{M_1}{E I} + \frac{P \cdot y}{E I} + \frac{V_1 \cdot x}{E I} \quad \ldots\ldots\ldots\ldots (4)$$

in which, *I* is the moment of inertia of the member. If the primary stress, *P*, is compression, the only change in Equation (4) is $-\frac{P \cdot y}{E I}$ instead of $+\frac{P \cdot y}{E I}$.

Let $\frac{P}{E I} = Q^2$, which is, therefore, a constant as long as the condition of loading remains.

Equation (4) now becomes:

$$\frac{d^2 y}{d x^2} - Q^2 \cdot y = -\frac{M_1}{E I} + \frac{V_1 \cdot x}{E I} \quad \ldots\ldots\ldots\ldots\ldots\ldots (5)$$

This is a standard differential equation, solved by finding (*a*) its complementary function by assuming $y = e^{mx}$; and (*b*) its particular integral by inspection.

The solution is:

$$y = C_1 \cdot e^{+Qx} + C_2 \cdot e^{-Qx} + \frac{M_1}{P} - \frac{V_1 x}{P} \quad \ldots\ldots\ldots\ldots\ldots (6)$$

in which, C_1 and C_2 are constants to be determined from the end conditions. As $y = 0$ both when $x = 0$ and when $x = L$,

$$C_1 = -\frac{M_1}{P} \cdot \frac{(1 - e^{-QL})}{(e^{+QL} - e^{-QL})} + \frac{V_1 L}{P} \cdot \frac{1}{(e^{+QL} - e^{-QL})} \quad \ldots\ldots(7)$$

and,

$$C_2 = +\frac{M_1}{P} \cdot \frac{(1 - e^{-QL})}{(e^{+QL} - e^{-QL})} - \frac{V_1 L}{P} \cdot \frac{1}{(e^{+QL} - e^{-QL})} \quad \ldots\ldots(8)$$

The slope of the elastic line at any point, N, is:

$$\frac{d\,y}{d\,x} = +\,Q\,C_1\,e^{+Qx} - Q\,C_2\,e^{-Qx} - \frac{V_1}{P} \quad \ldots\ldots(9)$$

but,

$$r_1 = \frac{d\,y}{d\,x} \text{ for } x = 0, \text{ and } r_2 = \frac{d\,y}{d\,x} \text{ for } x = L$$

hence,

$$r_1 = +\,Q\,C_1 - Q\,C_2 - \frac{V_1}{P} \quad \ldots\ldots(10)$$

and,

$$r_2 = +\,Q\,C_1\,e^{+QL} + Q\,C_2\,e^{-QL} - \frac{V_1}{P} \quad \ldots\ldots(11)$$

after substitution in Equation (9).

On substituting the values of C_1 and C_2 found from Equation (7) and Equation (8) in Equation (10) and Equation (11):

$$r_1 = \frac{M_1}{P} \cdot Q \cdot \frac{(e^{+QL} - 1)}{(e^{+QL} + 1)} + \frac{V_1}{P}\left(\frac{2}{e^{+QL} - e^{-QL}} \cdot QL - 1\right) \quad \ldots\ldots(12)$$

and

$$r_2 = \frac{M_1}{P} \cdot Q \cdot \frac{(e^{+QL} - 1)}{(e^{+QL} + 1)} + \frac{V_1}{P}\left(\frac{e^{+QL} + e^{-QL}}{e^{+QL} - e^{-QL}} \cdot Q\,L - 1\right) \quad \ldots\ldots(13)$$

Making use of hyperbolic functions, these equations become:

$$r_1 = \frac{M_1}{P} \cdot Q \tanh \cdot \frac{Q\,L}{2} + \frac{V_1}{P}\left(\frac{1}{\sinh \cdot Q\,L} \cdot Q\,L - 1\right) \quad \ldots\ldots(14)$$

$$r_2 = \frac{M_1}{P} \cdot Q \tanh \cdot \frac{Q\,L}{2} + \frac{V_1}{P}\left(\frac{\cosh \cdot Q\,L}{\sinh \cdot Q\,L} \cdot Q\,L - 1\right) \quad \ldots\ldots(15)$$

Eliminating V_1 from Equation (14) and Equation (15), a relation is found between M_1 and the deflection angles, r_1 and r_2. This is:

$$M_1 = \frac{2\,E\,I}{L}(2\,a\,r_1 + b\,r_2) \quad \ldots\ldots(16)$$

in which,

$$a = \frac{1}{8}\left(\frac{Q^2 L^2}{Q\,L \coth \cdot \frac{Q\,L}{2} - 2} + Q\,L \cdot \coth \cdot \frac{Q\,L}{2}\right)$$

and,

$$b = \frac{1}{4}\left(\frac{Q^2 L^2}{Q\,L \coth \cdot \frac{Q\,L}{2} - 2} - Q\,L \cdot \coth \cdot \frac{Q\,L}{2}\right)$$

Replacing M_1 by M_2 and interchanging τ_1 and τ_2,

$$M_2 = \frac{2\,E\,I}{L}\,(2\,a\,\tau_2 + b\,\tau_1) \quad \ldots\ldots\ldots\ldots\ldots\ldots (17)$$

These values of a and b may be expressed in the form of infinite series by the use of the known series:

$$\coth .\, x = \frac{1}{x} + \frac{x}{3} - \frac{x^3}{45} + \frac{2\,x^5}{945}, \text{ etc.,} \quad \ldots\ldots\ldots\ldots (18)$$

Thus,

$$a = 1 + \frac{(Q\,L)^2}{30} - \frac{11\,(Q\,L)^4}{25\ 000} +, \text{ etc.,} \quad \ldots\ldots\ldots\ldots (19)$$

$$b = 1 - \frac{(Q\,L)^2}{60} + \frac{13\,(Q\,L)^4}{25\ 000} -, \text{ etc.,} \quad \ldots\ldots\ldots\ldots (20)$$

Equation (19) and Equation (20) are for the case of P as tension. If P is compression, Q^2 is negative, and the signs of the terms in the even places in Equation (19) and Equation (20) must be changed, as follows:

$$a = 1 - \frac{(Q\,L)^2}{30} - \frac{11\,(Q\,L)^4}{25\ 000}, \text{ etc.,} \quad \ldots\ldots\ldots\ldots (21)$$

$$b = 1 + \frac{(Q\,L)^2}{60} + \frac{13\,(Q\,L)^4}{25\ 000}, \text{ etc.,} \quad \ldots\ldots\ldots\ldots (22)$$

Summarizing, the fundamental deflection formulas are:

$$\left.\begin{aligned} M_{12} &= \frac{2\,E\,I}{L}\,(2\,a\,\tau_{12} + b\,\tau_{21}) \\ M_{21} &= \frac{2\,E\,I}{L}\,(2\,a\,\tau_{21} + b\,\tau_{12}) \end{aligned}\right\} \quad \ldots\ldots\ldots\ldots (23)$$

in which,

$$\left.\begin{aligned} a &= 1 \pm \frac{(Q\,L)^2}{30} - \frac{11\,(Q\,L)^4}{25\ 000} \pm \ldots \\ b &= 1 \mp \frac{(Q\,L)^2}{60} + \frac{13\,(Q\,L)^4}{25\ 000} \mp \ldots \end{aligned}\right\} \quad \ldots\ldots\ldots\ldots (24)$$

the upper signs in Equation (24) being used when P is tension, and the lower when P is compression.

A slight change in the notation has been introduced. The member, AB, is called 12, and the bending moment and deflection angle at End 1 are denoted by M_{12} and τ_{12}, respectively, while those of End 2 are M_{21} and τ_{21}, respectively.

Expressing τ_1 and τ_2 in terms of M_{12} and M_{21}, Equation (23) will give:

$$\left.\begin{aligned} \tau_{12} &= \frac{L}{6\,E\,I}\,(2\,c\,M_{12} - d\,M_{21}) \\ \text{and,} \qquad \tau_{21} &= \frac{L}{6\,E\,I}\,(2\,c\,M_{21} - d\,M_{12}) \end{aligned}\right\} \quad \ldots\ldots\ldots\ldots (25)$$

in which,

$$c = 1 \mp \frac{(Q\,L)^2}{15} + 2\,(Q\,L)^4 \mp \frac{(Q\,L)^6}{1\ 575} + \cdots$$

and,

$$d = 1 \mp \frac{7\,(Q\,L)^2}{60} + \frac{3\,(Q\,L)^4}{2\ 520} \mp \frac{127\,(Q\,L)^6}{100\ 800} + \cdots \quad \Big\} \ldots\ldots\ldots (26)$$

the upper signs in Equation (26) being used when P is tension, and the lower when P is compression.

Relation Between the Deflection Angles of Members Meeting in a Joint.—Let any number of members, $n1$, $n2 \ldots nm$, meet at a joint, n. It may readily be shown* that the τ of any of these members can be expressed in terms of the τ of any other, chosen for purpose of reference, and the angular changes taking place between the different members at n.

In general,

$$\tau_{nm} = \tau_{n1} + \sum_{1}^{m-1} \Delta\,\alpha \ldots\ldots\ldots\ldots\ldots\ldots\ldots (27)$$

It is usually convenient to take as the reference, τ, that of the member first reached in passing around the joint from the outside of the frame in a clockwise direction.

The Sum of the Bending Moments About Any Joint is Zero.—In order to find these unknown τ's, use is made of the fact that each joint is in equilibrium under all the bending moments about the joint. If an eccentric external force were present, it can be accounted for, too, but for the time being it is assumed that there is none.

Hence, from Fig. 6:

$$M_{n_1} + M_{n_2} + \ldots + M_{nm} = 0 \ldots\ldots\ldots\ldots\ldots\ldots\ldots (28)$$

in which, M_{n_1} is the moment at n in Member $n1$, etc.

Referring now to Equation (23):

$$M_{n1} = \frac{2\,E\,I_{n1}}{L_{n1}}\,(2\,a_{n1}\,\tau_{n1} + b_{\,n1}\,\tau_{1n})$$

in which,

I_{n_1} = the moment of inertia of Member $n1$;
L_{n_1} = the length of Member $n1$;
τ_{n1} = the deflection angle of Member $n1$ at End n;
τ_{1n} = the deflection angle of Member $n1$ at End 1.

$$a_{n1} = 1 \pm \frac{(Q_{n1}\,L_{n1})^2}{30} - \frac{11\,(Q_{n1}\,L_{n1})^4}{25\ 000} \pm \cdots$$

$$b_{n1} = 1 \mp \frac{(Q_{n1}\,L_{n1})^2}{60} + \frac{13\,(Q_{n1}\,L_{n1})^4}{25\ 000} \mp \cdots$$

the upper signs being used when P is tension, and the lower when P is compression, a and b being constants.

$$Q_{n1}{}^2 = \frac{P_{n1}}{E\,I_{n1}}$$

in which, P_{n_1} is the total primary stress transmitted by Member $n1$.

* "Modern Framed Structures," by Messrs. Johnson, Bryan and Turneaure, Part II.

Similarly,

$$M_{n2} = \frac{2\,E\,I_{n2}}{L_{n2}}\,(2\,a_{n2}\,\tau_{n2} + b_{n2}\,\tau_{2n})$$

in which the various quantities have exactly the same significance as before, and so on for the other bending moments.

There is, therefore, for every joint an equation that will contain the deflection angles of all the members that enter the joint. Furthermore, this equation is linear. For example, Equation (28) will take the form:

$$\left.\begin{aligned} &c_{n1}\,\tau_{n1} + c_{n2}\,\tau_{n2} + c_{n3}\,\tau_{n3} + c_{n4}\,\tau_{n4} + \cdots \\ &+ c_{1n}\,\tau_{1n} + c_{2n}\,\tau_{2n} + c_{3n}\,\tau_{3n} + c_{4n}\,\tau_{4n} + \cdots = 0 \end{aligned}\right\} \quad \cdots\cdots\cdots(29)$$

in which, c_{n_1}, etc., are constants.

Referring now to Equation (27), the τ's of Equation (29) must be changed into what are termed the "reference deflection angles" of the joints, of which Equation (29) makes use. For the purpose of consistency, take each member separately in a clockwise direction around every joint beginning outside the truss; the τ of the member first met will be the reference deflection angle of the joint. Taking τ_{n_1} of Equation (29) as the reference deflection angle of the joint, n (Fig. 6), call it τ_n. Making use of Equation (27),

$$\tau_{n2} = \tau_n + \Delta\,\alpha_{1n2}$$

in which, α_{1n_2} is the angle between $1n$ and $2n$,

$$\tau_{n3} = \tau_n + \Delta\,\alpha_{1n2} + \Delta\alpha_{2n3}, \text{ etc.},$$

while,

$$\tau_{1n} = \tau_1 + \Sigma\,\Delta\,\alpha_1,$$

in which, τ_1 is the reference deflection angle for Joint (1), and $\Sigma\,\Delta\,\alpha_1$ is the sum of the changes of angles that lie between the reference member of Joint (1) and the member, $n1$, etc.

Summarizing, it is possible to change Equation (29) into an equation, as follows:

$$k_n\,\tau_n + k_1\,\tau_1 + k_2\,\tau_2 + k_3\,\tau_3 + k_4\,\tau_4 + \cdots S = 0 \quad \cdots\cdots\cdots(30)$$

in which, all the k's and S's are constants.

A repetition of this for every joint will finally give a set of simultaneous linear equations, equal in number to the joints, and the unknowns are the reference deflection angles. On solving these, substitute the values in Equation (27) to determine all the deflection angles in the truss. Making use of the latter in Equation (23), the two bending moments at the ends of every member are found. A check must be applied here; the sum of the bending moments at every joint must be zero. If this is satisfactorily done, the secondary stresses are obtained from the formula,

$$f = \frac{M\,y}{I},$$

in which,

f = the secondary stress;
M = the bending moment at one end of a particular member;
y = the distance of the extreme fiber from the center of gravity; and
I = the moment of inertia of the member in question.

It must be remembered that the extreme fiber represents the set of extreme fibers that lie in a plane parallel to the neutral plane of the member.

Mathematically, the problem is solved. In practice, however, the labor is excessive; certain approximations, therefore, are necessary.

2.—Modification of Manderla's Method

An improvement in Manderla's method is due to Winkler. The analysis is much the same as that just explained with no change as far as the derivation of Equation (3).

The Bending Moments Introduced at the Joints.—According to Equation (3) and Fig. 5:

$$M_x = M_1 - Py - V_1 x_1$$

Now, y, the offset of N from the line, A-B, is generally so small that $-Py$ may be neglected. Therefore,

$$M_x = M_1 - V_1 x \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (31)$$

giving rise to the following equation of the elastic line:

$$E\,I\,.\,\frac{d^2\,y}{d\,x^2} = V_1\,x - M_1 \ldots\ldots\ldots\ldots\ldots\ldots\ldots (32)$$

Equation (32) can be easily solved by direct integration. Integrating once with respect to x,

$$E\,I\,\frac{d\,y}{d\,x} = +\frac{V_1\,x^2}{2} - M_1\,x + C \ldots\ldots\ldots\ldots\ldots (33)$$

which represents the slope of the elastic line at any point, N, distant x from A. The constant, C, will be determined later. Integrating again,

$$E\,I\,.\,y = +\frac{V_1\,x^3}{6} - \frac{M_1\,x^2}{2} + C\,x + D \ldots\ldots\ldots\ldots (34)$$

which gives the distance of the point, N, from AB. The constants, C and D, are now determined from the fact that $y = 0$ when $x = 0$ and $x = L$. Therefore,

$$D = 0, \text{ and } C = +\frac{M_1\,L}{2} - \frac{V_1\,L^2}{6}$$

Substituting now in Equation (33), the equation of the slope of the elastic line becomes:

$$E\,I\,.\,\frac{d\,y}{d\,x} = +\frac{V_1\,x^2}{2} - M_1\,x + \frac{M_1\,L}{2} - \frac{V_1\,L^2}{6} \ldots\ldots\ldots\ldots (35)$$

The slope at $x = 0$ is the deflection angle, τ_1. Hence,

$$E\,I\,.\,\tau_1 = +\frac{M_1\,L}{2} - \frac{V_1\,L^2}{6} \ldots\ldots\ldots\ldots\ldots\ldots (36)$$

The moments about B are now taken, giving $V_1\,L = M_1 + M_2$. Hence, Equation (36) becomes:

$$\tau_1 = \frac{L}{6\,E\,I}\,(2\,M_1 - M_2) \ldots\ldots\ldots\ldots\ldots\ldots (37)$$

Starting at the other end of the member, there would have resulted a similar expression,

$$\tau_2 = \frac{L}{6\,E\,I}(2\,M_2 - M_1) \qquad (38)$$

(Compare Equations (37) and (38) with Equations (25); the difference is that the c and d of Equations (25) are each replaced by unity in Equations (37) and (38). In other words, the Q in Equations (26) is here considered as zero, that is, the force, P, is regarded as zero. That is exactly what would be expected, for at the start of this analysis the effect of the direct stress on the bending moments was disregarded.)

Making use of Equations (37) and (38) to express M_1 and M_2 in terms of τ_1 and τ_2:

$$\left.\begin{aligned} M_1 &= \frac{2\,E\,I}{L}(2\,\tau_1 + \tau_2) \\ M_2 &= \frac{2\,E\,I}{L}(2\,\tau_2 + \tau_1) \end{aligned}\right\} \qquad (39)$$

(Again, comparing with Equations (23), it is evident that the a and b are each replaced by unity, for the same reasons that c and d were.)

Relation Between the Deflection Angles of Members Meeting in a Joint.—This is the same as was given for Manderla's original method.

The Sum of the Bending Moments Around Any Joint is Zero.—Again, as previously (see Fig. 6):

$$M_{n1} + M_{n2} + M_{n3} + M_{n4} = 0$$

Making use of Equations (39), this becomes:

$$\left.\begin{aligned} &\frac{2\,E\,I_{n1}}{L_{n1}}(2\,\tau_{n1} + \tau_{1n}) + \frac{2\,E\,I_{n2}}{L_{n2}}(2\,\tau_{n2} + \tau_{2n}) \\ &+ \frac{2\,E\,I_{n3}}{L_{n3}}(2\,\tau_{n3} + \tau_{3n}) + \frac{2\,E\,I_{n4}}{L_{n4}}(2\,\tau_{n4} + \tau_{4n}) = 0 \end{aligned}\right\} \qquad (40)$$

Let the quantity, $\frac{I}{L}$, be called K. Hence,

$$\begin{aligned} K_{n1}(2\,\tau_{n1} + \tau_{1n}) + K_{n2}(2\,\tau_{n2} + \tau_{2n}) + K_{n3}(2\,\tau_{n3} + \tau_{3n}) \\ + K_{n4}(2\,\tau_{n4} + \tau_{4n}) = 0 \end{aligned} \qquad (41)$$

Use may then be made of the reference deflection angles. Thus, in Fig. 6, the τ of the joint, n, is τ_{n1}, which without fear of confusion may be called τ_n, while τ_{n2} becomes $\tau_n + \Delta\,\alpha$, τ_{n3} becomes $\tau_n + \Delta\,\alpha + \Delta\,\beta$, etc. (See Equation (27)).

As many equations of the type of Equation (41) are found as there are joints. There will be a large number of τ's of the nature, τ_{n1}, τ_{n2} .... τ_{1n}, τ_{2n} ...., etc., but by making use of Equation (27), there results finally a set of as many simultaneous linear equations in the reference τ's as there are joints. After solving these, Equation (39) will express the bending moments at the ends of all the members. Finally, the use of the equation, $f = \frac{M\,y}{I}$, gives the required secondary stresses.

Professor Turneaure's method will be followed in arriving at the set of simultaneous linear equations for the τ's, and the steps that lead to the equations with comparative ease will be explained more fully in the practical application which Manderla's original method lacked.

It is evident that the value of E does not affect the secondary stresses, for the simple reason that in this analysis E appears in the denominator of an expression in one place, only to be cancelled out in the numerator later. As all the methods that will be applied show this property, E will be considered as unity throughout. It is another matter, of course, in testing the theory in the field; there, in determining what stress a certain deformation represents, E is essential.

Manderla solves his simultaneous equations by a method of approximation. It will be found that the coefficient of one of the τ's in every equation (the one belonging to the reference, τ, of the joint for which that particular equation is formed) is much larger than any of the others. By first imagining all the small coefficients to be zero, approximate values are obtained for the τ's that are retained. Taking each equation as given, and substituting in all the terms except that with the large coefficient the approximate values of the τ's just found, a fresh set of values for the τ's is determined. This process is repeated until a stage is reached where the τ's of the final approximation differ little from those of the previous approximation—these are then the values required. This method lends itself to slide-rule computation and is, therefore, much in favor with engineers; the great objection is that many approximations are necessary when there are many joints—a tedious task. This method, however, will be illustrated by an example.

Professor Turneaure has a definite method of elimination (25). Winkler has also given such a method (4). Several investigators have noted the fact that all these sets of simultaneous equations are, as they appear, of the type known as Gauss' normal equations. Most books on least squares describe Gauss' method of solving a set of simultaneous linear equations, in which he re-arranges them in what he calls the "normal" form, to which he then applies a most effective and absolutely self-checking method of solution. A solution of secondary stresses, using Gauss' method of normal equations, will also be given.

3.—Müller-Breslau's Method

Introduction.—A simple truss made up of triangular elements is such that, if it has n joints, the number of members is $(2n\text{-}3)$. This is the criterion of what is known as a statically determinate plane framework. In the present problem every member has a certain bending moment at each end; these bending moments are really the unknown quantities that are to be determined. Their number is, therefore, $2\ (2n\text{-}3) = (4n\text{-}6)$.

The underlying principles of this method are exactly those of the modified Manderla method; the manner of attacking the problem is different. As many linear equations as there are joints are obtained from the property that the sum of the moments about a joint is zero. As will be shown later, there are three independent linear relations between the three changes of angle in every

triangular element and the six moments, two for each of the three sides. As there are $(n\text{-}2)$ triangular elements, the total number of these relations is $3\ (n\text{-}2) = (3\,n\text{-}6)$. There are, therefore, $n + (3\,n\text{-}6) = (4\,n\text{-}6)$ linear equations to solve the $(4\,n\text{-}6)$ unknown bending moments.

Manderla has this number of equations too, but, by making use of the fact that all the deflection angles at a joint can be expressed in terms of one at that joint, he is able to tie up, as it were, the $(3n\text{-}6)$ relations in the n simultaneous equations; after these are solved he reverts to the expression for all the τ's at a joint in terms of the one, and then uses the remaining $(3\,n\text{-}6)$ relations.

Müller-Breslau has a special way of setting down the total $(4\,n\text{-}6)$ relations, one after the other. By assuming two particular bending moments at the left end of a truss to be known, he proceeds to express every successive one in terms of the preceding ones until, finally, he arrives at two equations in which every bending moment is already in terms of the two assumed ones. In other words, he obtains two linear equations with which to find the bending moments. Repeating the work and substituting these in the expressions, all the bending moments become known. It is a neat method of elimination.

All moments in a clockwise direction will be reckoned positive in this method.

Procedure.—A triangle, *ABC* (Fig. 7) under such a system of moments will be bent in a form as shown. Hence,

$$\tau_2 + \alpha + \Delta\alpha = \tau_3 + \alpha.$$

Therefore,

$$\Delta\alpha = \tau_3 - \tau_2.$$

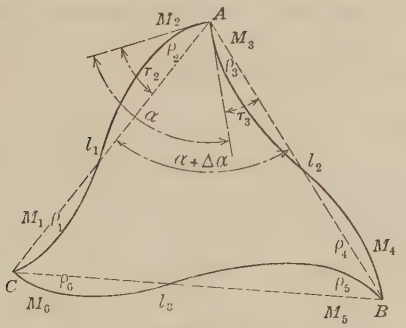

FIG. 7.

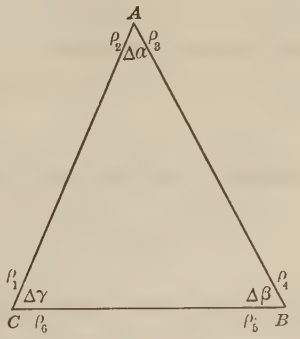

FIG. 8.

From Equation (37) however:

$$\tau_2 = 2\ M_2 - \frac{M_1}{6\ E\ I_1} \cdot l_1$$

and,

$$\tau_3 = 2\ M_3 - \frac{M_4}{6\ E\ I_2} \cdot l_2$$

(The analysis for the deflection angles in terms of the end bending moments is of course the same as that used in the modified Manderla method. Note that Müller-Breslau also neglects the effect of the primary stress on the bending moment.)

Therefore,

$$\Delta\alpha = 2M_3 - \frac{M_4}{6EI_2}\cdot l_2 - 2M_2 - \frac{M_1}{6EI_1}\cdot l_1 \quad \ldots\ldots(42)$$

For convenience let,

$$\frac{M_1 l_1}{I_1} = \rho_1;\ \frac{M_2 l_1}{I_1} = \rho_2;\ \frac{M_3 l_2}{I_2} = \rho_3;$$
$$\frac{M_4 l_2}{I_2} = \rho_4;\ \frac{M_5 l_3}{I_3} = \rho_5;\ \frac{M_6 l_3}{I_3} = \rho_6$$

Insert these expressions in Equation (42) and multiply by $6E$, obtaining:

$$6E.\Delta\alpha = (2\rho_3 - \rho_4) - (2\rho_2 - \rho_1),$$

or,

$$6E.\Delta\alpha = \rho_1 - 2(\rho_2 - \rho_3) - \rho_4 \quad \ldots\ldots(43)$$

Similarly,

$$6E.\Delta\beta = \rho_3 - 2(\rho_4 - \rho_5) - \rho_6 \quad \ldots\ldots(44)$$

and,

$$6E.\Delta\gamma = \rho_5 - 2(\rho_6 - \rho_1) - \rho_2 \quad \ldots\ldots(45)$$

Between the changes of the angle, $\Delta\alpha$, $\Delta\beta$, and $\Delta\gamma$, of the triangle there exists the relation:

$$\Delta\alpha + \Delta\beta + \Delta\gamma = 0$$

or,

$$\rho_1 - \rho_2 + \rho_3 - \rho_4 + \rho_5 - \rho_6 = 0 \quad \ldots\ldots(46)$$

Express ρ_4, ρ_5, and ρ_6, in terms of ρ_1, ρ_2, and ρ_3, and the changes of angle. Hence Equation (43) gives:

$$\rho_4 = -6E.\Delta\alpha + \rho_1 - 2(\rho_2 - \rho_3)$$

or,

$$(2\rho_3 - \rho_4) = 6E\Delta\alpha + (2\rho_2 - \rho_1) \quad \ldots\ldots(47)$$

Equations (44) and (46) give:

$$\rho_5 = 6E\Delta\beta + (\rho_1 - \rho_2) + \rho_4$$

or,

$$(\rho_5 - \rho_4) = 6E\Delta\beta + (\rho_1 - \rho_2) \quad \ldots\ldots(48)$$

and Equations (45) and (46) give:

$$\rho_6 = 6E\Delta\gamma - (\rho_3 - \rho_4) + \rho_1$$

or,

$$(\rho_1 - \rho_6) = 6E\Delta\gamma + (\rho_3 - \rho_4) \quad \ldots\ldots(49)$$

In using Equations (47), (48), and (49), it is convenient to bear in mind the following rules:

1.—When any three adjacent values, ρ_1, ρ_2, and ρ_3, are known, the value, ρ_4, is readily obtained by Equation (47), in which $(2\rho_3 - \rho_4)$ is the deflection angle of AB at A, that is, of the member first met in passing around the

joint, A, in a clockwise direction, and $(2\rho_2 - \rho_1)$ is the deflection angle of AC at A.

2.—When any four adjacent values, ρ_1, ρ_2, ρ_3, and ρ_4, are given, a fifth value, ρ_5 or ρ_6, may be found from Equation (48) or Equation (49), in which $(\rho_5 - \rho_4)$ is the difference of the ρ-values at B of the sides, BC and BA, which include the angle, B, and $(\rho_1 - \rho_2)$ is the difference of the values of the side, AC, opposite to B.

In both cases the difference is found by passing around the joint in a clockwise direction and then subtracting the second one of the values in question from the first.

Equations (47), (48), and (49) and the three fundamental equations, one for each joint, namely, that the sum of the bending moments around each joint is zero, comprise six independent relations between the six unknowns, $\rho_1 \ldots \rho_6$, which therefore can be determined.

(This is for the case of a structure composed of a single triangle. Note that the changes of angle are previously determined in exactly the same manner as was shown for Manderla's method.)

If instead of a single triangle the structure is as shown in Fig. 9, the process of calculating the values, $\rho_1 \ldots \rho_{14}$, is as follows: Consider any Joint (1) in which only two members intersect, and assume for the present that the ρ_1 and ρ_2 of the member, 1-2, are known.

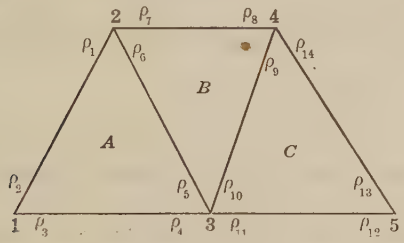

FIG. 9.

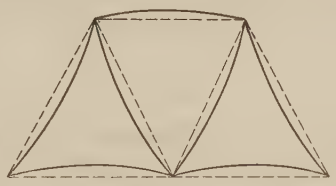

FIG. 10.

The fundamental equation, $M = 0$, for Joint (1) gives:

$$M = M_2 + M_3 = 0$$

Turning back to the notation adopted, this equation becomes

$$\rho_3 \cdot \frac{I_2}{l_2} = -\rho_2 \cdot \frac{I_1}{l_1}$$

After ρ_3 is known, its value is substituted in Equation (47), thus giving ρ_4 as a function of ρ_1 and ρ_2. By substituting the values of ρ_3 and ρ_4 in Equations (48) and (49), ρ_5 and ρ_6 also are expressed in terms of ρ_1 and ρ_2.

In passing to Joint (2), ρ_7 is the only quantity not known; but,

$$M = M_7 + M_6 + M_1 = 0$$

or,

$$\rho_7 \cdot \frac{I_4}{l_4} + \rho_6 \cdot \frac{I_3}{l_3} + \rho_1 \cdot \frac{I_1}{l_1} = 0$$

whence, ρ_7 is expressed in terms of ρ_1 and ρ_2.

By applying Equations (47), (48), and (49) to the triangle, B, of which ρ_5, ρ_6, and ρ_7 are now expressed in terms of ρ_1 and ρ_2, the remaining quantities, ρ_8, ρ_9, and ρ_{10}, may first be expressed in terms of ρ_5, ρ_6, and ρ_7, and then, in turn, in terms of ρ_1 and ρ_2.

Knowing ρ_4, ρ_5, and ρ_{10}, ρ_{11} at Joint (3) is found from,

$$M_4 + M_5 + M_{10} + M_{11} = 0$$

and, finally, ρ_{12}, ρ_{13}, and ρ_{14}, are found by means of Equations (47), (48), and (49), which are to be applied to the triangle, C.

The preceding analysis shows that each ρ may be expressed as a linear function of ρ_1 and ρ_2, which were assumed to be known at the start. There are two equations left that have not been used, namely,

$$\Sigma M_{(4)} = \Sigma M_{(5)} = 0$$

These are:

$$\left.\begin{aligned} \rho_{14} \cdot \frac{I_7}{l_7} + \rho_9 \cdot \frac{I_5}{l_5} + \rho_8 \cdot \frac{I_4}{l_4} &= 0 \\ \text{and,} \qquad \rho_{12} \cdot \frac{I_6}{l_6} + \rho_{13} \cdot \frac{I_7}{l_7} &= 0 \end{aligned}\right\} \quad \ldots\ldots\ldots\ldots\ldots (50)$$

Making use of the expressions for ρ_{14}, etc., in terms of ρ_1 and ρ_2, Equations (50) become two simultaneous linear equations in terms of ρ_1 and ρ_2 which are then solved. All the other ρ's, therefore, are also determined. The secondary stress, f, is then found from,

$$f = \frac{M\,y}{I} = \rho \cdot \frac{I}{l} \cdot \frac{y}{I} = \rho \cdot \frac{y}{l} \quad \ldots\ldots\ldots\ldots\ldots (51)$$

in which, y is the distance of the extreme fiber from the center of gravity and l is the length of the member.

Remarks.—Müller-Breslau's method is not exactly like this one, which is due to Pácz. Müller-Breslau assumes that the triangles alternate in shape as in Fig. 10.

This requires a changing of signs in the moments passing from one triangle to the next, a method that is apt to create confusion and is the source of many errors. The method of Páez is to reckon all the moments to be positive and to remain positive in the analysis. It is then known what shapes the triangles assume theoretically. If, in the calculations, a moment at one end of a member is found to be negative the shape of the member should be contrary to that assumed. Thus, Pácz' modification is far superior in that the signs are taken care of in the work.

4.—Ritter's Method.

Introduction.—The graphical method of computing secondary stresses developed by Ritter is also based on the fundamental equation of Manderla. Its aim is to solve graphically the $(4n\text{-}6)$ equations for the $(4n\text{-}6)$ bending moments, one at each end of every member.

Procedure.—Consider any joint of a structure as Joint (5) in Fig. 11, at which the four members, 5-3, 5-4, 5-6, and 5-7, meet. Imagine all the members to be bent under positive (clockwise) bending moments. The two bending moments of the member, 3-5, are designated M_3 at Joint (5) and M_3' at Joint (3). For the member, 4-5, the moments are M_4 at Joint (5) and M_4' at Joint (4), etc. When Joint (4) is considered, the bending moments of the member, 4-5, are M_5 at Joint (5) and M_5' at Joint (5).

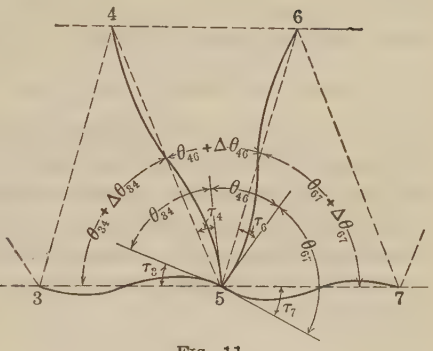

FIG. 11.

It follows, therefore, that:

$$M_4 \text{ for Joint (5)} = M_5' \text{ for Joint (4)}$$
$$M_4' \text{ " " (5)} = M_5 \text{ " " (4)}$$

which means that each moment in a truss is designated in two different ways.

From Fig. 11,

$$\theta_{3.4} + \Delta\,\theta_{3.4} + \tau_4 = \theta_{3.4} + \tau_3$$

or,

$$\Delta\,\theta_{3.4} = \tau_3 - \tau_4$$

Substituting the values of τ_3 and τ_4 as found from Equation (37),

$$E \cdot \Delta\,\theta_{3.4} = \frac{2\,M_3 - M_3'}{6\,I_3} \cdot l_3 - \frac{2\,M_4 - M_4'}{6\,I_4} \cdot l_4$$

in which, M_3 and M_4 are the moments at the near ends, and M_3' and M_4' those at the far ends of the members, 5-3 and 5-4, which include the angle, $\theta_{3.4}$. Similar expressions can be written for $E \cdot \Delta\,\theta_{4.6}$ and $E \cdot \Delta\,\theta_{6.7}$.

The sum of the moments around Point (5) is zero and, therefore,

$$M_3 + M_4 + M_6 + M_7 = 0.$$

For convenience, let $\frac{M\,l}{6\,I} = \mu$. The four equations connected with Joint (5) can now be written as follows:

$$\left.\begin{aligned} E \cdot \Delta\,\theta_{3.4} &= (2\,\mu_3 - \mu_3') - (2\,\mu_4 - \mu_4') \\ E \cdot \Delta\,\theta_{4.6} &= (2\,\mu_4 - \mu_4') - (2\,\mu_6 - \mu_6') \\ E \cdot \Delta\,\theta_{6.7} &= (2\,\mu_6 - \mu_6') - (2\,\mu_7 - \mu_7') \\ \frac{I_3}{l_3} \cdot \mu_3 + \frac{I_4}{l_4} \cdot \mu_4 + \frac{I_6}{l_6} \cdot \mu_6 + \frac{I_7}{l_7} \cdot \mu_7 &= 0 \end{aligned}\right\} \ldots\ldots\ldots (52)$$

For every joint there are as many equations as there are members intersecting at the joint. The total number of these equations is equal to the number of ends of all the members and, therefore, equal to that of the unknown μ-values.

The changes of angle are determined either graphically or analytically by Ritter's method as used previously,* and are, therefore, regarded as known.

* See p. 9.

In order to explain how Ritter solves his problem, assume all the μ'-values to be known for the present. The μ-values are then determined easily by force and equilibrium polygons, as follows:

Consider the values, $\frac{I}{l}$, as vertical forces; plot them in order on a vertical line and draw a force polygon with any arbitrary pole, Fig. 12. The distances, $E \cdot \Delta\theta$, between the forces are then laid out horizontally as shown in Fig. 13. Each of the forces is then displaced to the left by the amount, μ', that belongs to the member to which the so-called force corresponds. The equilibrium polygon is now constructed for these displaced forces. The distances of the displaced forces from their resultant will then be the double values of the μ's.

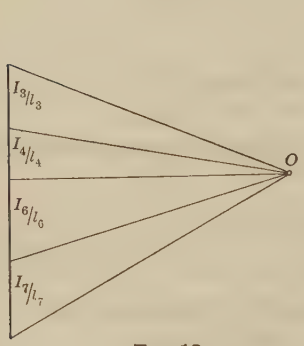

Fig. 12.

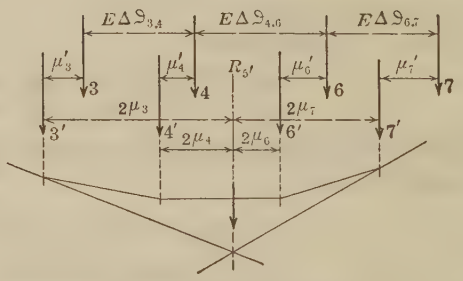

Fig. 13.

A study of Equations (52) and Fig. 13 will prove the truth of this statement. The distance of a displaced force from the resultant, is 2μ for a displacement, μ'; consequently, the distance of an undisplaced force from the resultant of the displaced forces is equal to $(2\mu - \mu')$, and the difference between the distances of two adjacent undisplaced forces must equal $E \cdot \Delta\theta$. The first three of the Equations (52) are, therefore, satisfied. The fourth is also satisfied, as the algebraic sum of the moments $(= \Sigma \frac{I}{l} \cdot 2\mu)$ of the parallel forces, $\frac{I}{l}$, about any point on the line of the resultant is equal to zero.

The difficulty, however, is that neither the μ-values nor the μ'-values are known. Let Figs. 14 and 15 represent the equilibrium polygons for Joints (4) and (5), R_4' and R_5', the resultants of the displaced forces, 2′, 3′ ..... If, now, the distance between an undisplaced force and the resultant of the displaced forces is denoted by γ, we have:

$$2\mu_4 = \mu_4' + \gamma_4$$
$$2\mu_5 = \mu_5' + \gamma_5$$

but,

$$\mu_4 = \mu_5' \text{ and } \mu_5 = \mu_4'$$

therefore,

$$2\,\mu_5' = \mu_4' + \gamma_4$$
$$2\,\mu_4' = \mu_5' + \gamma_5$$

By solving these equations:

and,

$$\left.\begin{aligned} \mu_4' &= \frac{(\gamma_4 + 2\,\gamma_5)}{3} \\ \mu_5' &= \frac{(\gamma_5 + 2\,\gamma_4)}{3} \end{aligned}\right\} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (53)$$

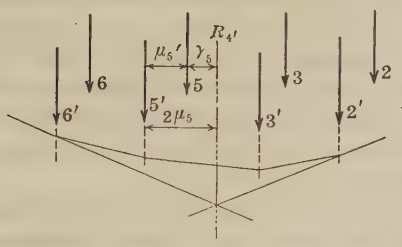

FIG. 14.

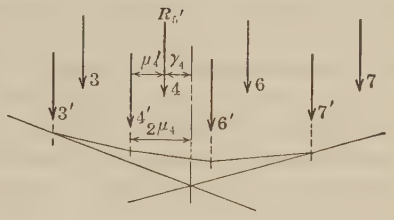

FIG. 15.

If the positions of the resultants, R_4' and R_5', of the displaced forces were known, the values of 2 μ could be found at once. These positions can only be found by trial. As the position of the resultant, R', undergoes little displacement (that is, the changes of the values, γ, are generally small), a roughly approximate position of the resultant, R', may be assumed as that of the resultant, R, of the undisplaced forces.

Measuring now the distances of the undisplaced forces from their resultant, and calling these distances the first approximation to the true γ's, these values are substituted in Equations (53) to give the first approximation to the μ's, the amounts by which the forces are displaced. Next determine the resultant of this first set of displaced forces.

The distances of the undisplaced forces to the resultant of the first set of displaced forces are the second approximation to the γ-values. Carrying through the process, a second resultant of displaced forces is found. This process is repeated several times, until it is found that, for every joint, the resultant of the displaced forces from the last trial differs very little from that of the former trial. The values of 2 μ are then the distances of the last set of displaced forces from their resultant.

The secondary stress is, therefore,

$$f = \frac{M\,y}{I} = \mu \cdot \frac{6\,I}{l} \cdot \frac{y}{I} = \frac{6\,y}{l} \cdot \mu \ldots\ldots\ldots\ldots\ldots\ldots (54)$$

Remarks.—In order to avoid errors strict attention must be paid to the signs of $\Delta\,\theta$, μ, and μ'. The succession of the members around a joint should be taken in a clockwise direction; a $\Delta\,\theta$ which has a positive sign should be laid out at the right, and a negative $\Delta\,\theta$ to the left. Further, any quantity, μ or μ', to be transferred into a corresponding equilibrium polygon should be

laid out to the left, if it is situated to the left of the resultant of the forces, $\frac{I}{l}$, and *vice versa*. Finally, the values, 2 μ, situated to the left of the resultant are positive and those to the right are negative.

5.—Mohr's Semi-Graphical Method

Introduction.—The preceding methods of Manderla, Müller-Breslau, and Ritter are based on the equations giving the changes of angle in the triangular elements, and on the equation arising from the fact that the sum of the bending moments around a joint is zero; these were the two sets of fundamental equations. In deriving his method, Mohr introduced two sets of angles, ψ and ϕ, on which the bending moments are dependent, thus avoiding in his computations the calculation of the changes of the angle, $\Delta\theta$, and of the deflection angles, τ, on which the previous methods depend. It is nevertheless true that this method can be easily changed into any of the others by establishing the relations between ψ and ϕ on the one hand and $\Delta\theta$ and τ on the other, and then substituting for ψ and ϕ in terms of $\Delta\theta$ and τ.

Let 1-2 (Fig. 16) represent any member before the exterior forces begin to act. Under the action of any loading the joints, 1 and 2, will be displaced to 1′ and 2′. The lines, 1′-2″ and 1″-2′, are parallel to each other and to the member, 1-2; 1′ T_1 and 2′ T_2 indicate the end tangents drawn to the elastic line of the curved member after deformation has taken place.

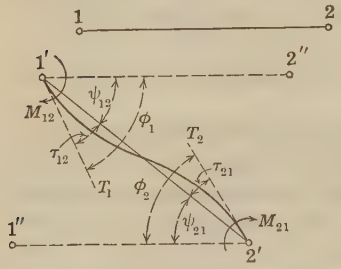

Fig. 16.

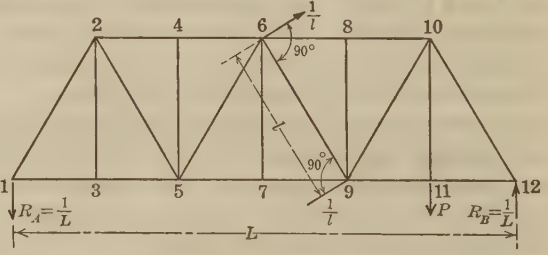

Fig. 17.

The angle, $2'' - 1' - 2' = \psi_{12} = \psi_{21}$, included between the original direction of the member and the chord, 1′-2′, of the curved member after deformation, is the angle through which a member turns under load, assuming that the truss is provided with frictionless joints. More clearly expressed, suppose the truss is one with frictionless joints; the load causes it to deflect, taking a member like 1-2 into a different position, namely, 1′-2′, the member remaining straight. Now, suppose that the gusset-plates at the ends, 1′ and 2′, start to act, introducing the bending moments, M_{12} and M_{21}, and causing the member to become curved. The assumption is that this bending takes place in such a manner, that the ends, 1 and 2, of the member are not moved. Mohr calls the angle, ψ_{12} and ψ_{21}, "the change in slope".

The angle, ϕ_1, included between the original direction, 1-2 or 1′-2″, of the member and its end tangent, 1′ T_1, is called by Mohr "the angle of rotation of the joint". This angle is the same for the ends of all members at

any joint, owing to the assumption that the ends are riveted rigidly together. In other words, the angle between any two members meeting at a joint is assumed to be constant during deformation of the truss.

To express the bending moments as functions of ϕ and ψ, start with the fundamental Equation (39),

$$M_{12} = \frac{2\,E\,I}{l} \cdot (2\,\tau_{12} + \tau_{21}).$$

From Fig. 16,

$$\tau_{12} = \phi_1 - \psi_{12},$$

and,

$$\tau_{21} = \phi_2 - \psi_{21} = \phi_2 - \psi_{12}.$$

Substituting these values in the fundamental equation,

$$\left.\begin{aligned} M_{12} &= \frac{2\,E\,I}{l} \cdot (2\,\phi_1 - 2\,\psi_{12} + \phi_2 - \psi_{12}) \\ \text{that is,} \quad M_{12} &= \frac{2\,E\,I}{l} \cdot (2\,\phi_1 + \phi_2 - 3\,\psi_{12}) \\ \text{and, similarly,} \quad M_{21} &= \frac{2\,E\,I}{l} \cdot (\phi_1 + 2\,\phi_2 - 3\,\psi_{12}) \end{aligned}\right\} \quad \ldots\ldots\ldots\ldots (55$$

The quantities, ψ, are really the properties of the truss considered as having frictionless joints, and are easily obtained as the truss is statically determinate. It has been proved that there is only one ϕ for each joint; also, the sum of the moments around a joint is zero. Hence, if this fact is expressed for each joint, making use of Equations (55), there will result as many simultaneous linear equations involving ϕ's as there are joints, that is, as there are ϕ's, the ψ's having been determined previously. These equations are solved for the ϕ's. The secondary stresses then follow easily.

Calculation of the Changes in the Slope, ψ.—This calculation may be done analytically or graphically.

(1).—Analytical Method.—The values of ψ are obtained analytically from the equation, $M\,\psi = \Sigma\, s \,.\, \Delta\, l$, or, by assuming $M = 1$,

$$1\,.\,\psi = \Sigma\, s\,.\,\Delta\, l \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (56)$$

in which, $M = 1$ designates any moment acting on a truss, s the stress in a member due to the moment, and ψ the angle of rotation of the member under the loads that produce the change in length, $\Delta\, l$, of the member in question.

Equation (56) follows from the theorem that, if a system in equilibrium is acted on by a set of external forces, thereby causing the system to move into another position of equilibrium, the work done by the external forces is equal to that done by the internal stresses, these stresses having been called into existence by the externally applied forces.

To illustrate the analytical method of determining s, consider the truss shown in Fig. 17. Suppose the change in the slope of the member, 6-9, under the action of the loading, P, at Joint (11), is required. For this purpose, first assume that P does not exist, but that two forces, $\frac{1}{l}$, act at the ends

of the member, 6-9, as shown (Fig. 17), introducing a couple of moment $= +1$. This moment requires a downward left-hand reaction, $\frac{1}{L}$, and an upward right-hand reaction of the same magnitude.

Compute the stresses, s, set up in the members under these two pairs of forces, namely, $\frac{1}{l}$ and $\frac{1}{L}$; also compute all the Δl-values of the members caused by the given loading, P, at Joint (11). The products, $s \cdot \Delta l$, are then computed for each member and added, giving the value, $\Sigma\, s \cdot \Delta l$, which is then the angle of revolution or change in the slope, ψ, of the member, 6-9, due to the load, P, at Joint (11).

It must be evident that the calculation of all the slopes of all the members—a process of repeating the method given as many times as there are members—is extremely laborious. It is safe to say that engineers will always avoid the analytical method and make use of the graphical, when the results are obtained with greater ease and reasonable accuracy.

(2).—Graphical Method.—The graphical method of determining the ψ-values consists in the construction of a Williot displacement diagram for the truss under the given loading, that is, the truss with the imaginary frictionless joints.

For the sake of simplicity consider any triangle, ABC, Fig. 18, and imagine that some loading produces the stresses, $-s_1$, $+s_2$, and $+s_3$, in BC, CA, and AB, thus changing their lengths, l_1, l_2, and l_3, by the amounts, $-\Delta l_1$, $+\Delta l_2$, and $+\Delta l_3$.

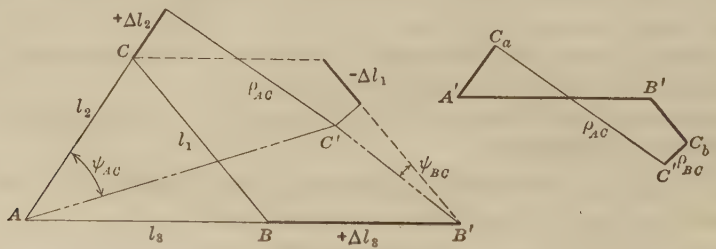

FIG. 18.

By regarding the joint, A, and the direction, A to B, as fixed, the displaced positions, B' and C', of B and C are found as shown. From Fig. 18, and also because the elastic deformations, Δl, of the members are small, so that the tangent of the arc may be substituted for the arc itself,

$$\rho_{AC} = l_2\, \psi_{AC}$$

or,

$$\psi_{AC} = \frac{\rho_{AC}}{l_2} \qquad (57)$$

The change in the slope, ψ_{AC}, of any member, AC, is, therefore, equal to the length, ρ_{AC}, of the perpendicular, $C_a\, C'$, to AC, which locates C', divided by the length, l_2, of AC. ψ is positive when the member turns in a clockwise direction.

If, instead of a single triangle, there is a truss composed of a series of triangles, the process of determining ψ for each member for any given loading will be the same, that is, by first constructing a displacement diagram (which gives the ρ-values), and by dividing the values of ρ of each member by its corresponding length, l.

The graphical method is more expeditious than the analytical method; besides, the construction of a displacement diagram is a process well known to engineers. For this reason the graphical method of computing ψ, which has been commonly used by previous computers, will be used here. In constructing a displacement diagram of a truss for any given loading, assume an arbitrary point, a, and an arbitrary direction, $a\,b$, as fixed. This generally gives different vertical displacements, θ_A and θ_B, for A and B, the points of supports. For the calculations of the vertical displacements of the panel points, it is necessary to introduce a correction (as suggested by Mohr), in the Williot diagram. The supports, A and B, Fig. 19, do not move vertically. In order to satisfy this condition in the displacement diagram, the truss must be rotated as a whole about A' or B' by an amount,

$$\psi'' = \frac{(\theta_B - \theta_A)}{L} \qquad (58)$$

thereby bringing $A'B'$ parallel to AB.

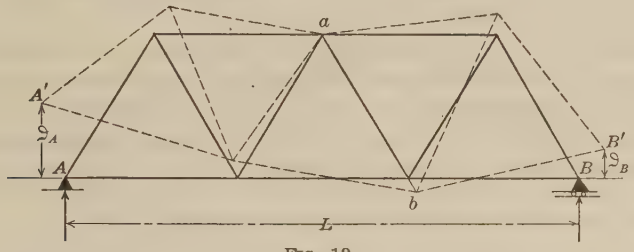

FIG. 19.

In the case of secondary stresses this is unnecessary. For the time being, however, suppose it is desirable to know the true angles, ψ and ϕ that is, the angles which the chord and the tangent line to a member at its one end, after loading, make with the direction of the member before loading. It will then be necessary to have a displacement diagram in which no relative vertical displacement between A and B has occurred. Therefore, the diagram as a whole must be rotated about either A or B by an amount, ψ'', as given in Equation (58). All values, ψ', obtained by means of the displacement diagram must be corrected by this amount, constant for a given loading, giving $\psi = \psi' + \psi''$, the true changes in the slopes with reference to the original direction of the members. The next step depends on whether it is desired to obtain only the secondary stresses, or also the correct values of ψ and ϕ for purposes of experimental verification.

It is the writer's opinion that it is better to omit this correction, to solve for the bending moments, and, if these satisfy the fundamental equations—that the sum of the bending moments about each joint is zero—then to add

the constant correction to all the ψ's and ϕ's in order to obtain the true quantities, this procedure only in the cases where experimental verification is to follow.

The reason why this correction is unnecessary is simple. The bending moment at one end of a member is (see Equation (55)):

$$M_{nm} = \frac{2\,E\,I}{l} \cdot (2\,\phi_n + \phi_m - 3\,\psi_{nm})$$

Deducting the constant quantity, ψ'', from both the ϕ's and the ψ, does not affect M_{nm}, because the correction is $2\psi'' + \psi'' - 3\,\psi''$. In other words, it is also true that:

$$M_{nm} = \frac{2\,E\,I}{l} \cdot (2\,\phi_{n'} + \phi_{m'} - 3\,\psi'_{nm}).$$

Hence, the use of the uncorrected values of ψ, namely, ψ', would give a set of simultaneous linear equations for the ϕ's, and these would have the property that they, too, differ from the true ϕ's by the constant amount, ψ''. As the secondary stresses depend on the M's, it is, therefore, justifiable to use the ψ''s and ϕ''s.

In this investigation it is intended to omit the prime marks, and designate the uncorrected changes of slope as ψ, and the uncorrected angles of rotation as ϕ, remembering that these, corrected by the constant quantity, ψ'', would give the values for investigation in the field.

Calculation of the ϕ's.—Assuming that the values, ψ, in Equation (55) have been found either analytically or graphically as indicated, the only real unknowns of the problem are, therefore, ϕ. The application of the fundamental equation, $\Sigma\, M = 0$, to each joint gives as many equations as there are joints, and unknowns, ϕ. Thus, for Joint (4), Fig. 17, by substituting the values of M as expressed in Equation (55) and putting $\frac{I}{l} = K$,

$$\Sigma\, M_{4\xi} = 2\,E\,(2\,\phi_4\,\Sigma\,K_{4\xi} + \Sigma\,\phi_\xi\,K_{4\xi} - 3\,\Sigma\,\psi_{4\xi}\,K_{4\xi}) = 0$$

or,

$$2\,\phi_4\,\Sigma\,K_{4\xi} + \Sigma\,\phi_\xi\,K_{4\xi} - 3\,\Sigma\,\psi_{4\xi} \cdot K_{4\xi} = 0 \quad \ldots\ldots\ldots\ldots (59)$$

in which the numbers of the adjacent joints—in this case 2, 3, 5, 7, 6—are to be substituted for the subscripts, ξ.

The solution of the n simultaneous linear equations of the form of Equation (59) gives the values of the n unknowns, ϕ, where n denotes the number of joints. It is important to note that these are again of the type known as Gauss' normal equations and may be solved according to his method.

Solution of the Stresses.—The next step consists in substituting the values, ϕ and ψ, in Equation (59), thus giving the values of the moments, M, acting at each end of every member. Before finding the secondary stresses, verify the values of the moments by applying the check, $\Sigma\, M = 0$, at each joint.

The secondary stress is then readily obtained from,

$$f = \frac{M\,y}{I} = 2\,E\,I\,(2\,\phi_a + \phi_n - 3\,\psi_{an})\,\frac{y}{l\,I}$$

or by putting $E = 1$,

$$f = \frac{2y}{l} \cdot (2\phi_a + \phi_n - 3\psi_{an}) \quad \ldots\ldots\ldots\ldots\ldots\ldots (60)$$

in which,

ϕ_a = the value of ϕ for the near end of the member;
ϕ_n = the value of ϕ for the far end of the member; and
ψ_{an} = the change in the slope of the member.

(Note that the ψ's from the deflection diagram are regarded as E multiplied by the true ψ's. The resulting ϕ's are, therefore, also the true ϕ's multiplied by E. Hence, although E is always regarded as equal to unity it will still give the true secondary stresses.)

6.—Mohr's Elastic Weight Method

Small Movements of a Chain of Elastic Weights.—In Fig. 20, 1, 2, 3, 4 ...., represent the joints of a plane chain of members. These members are caused to move in the plane while Joint (1) remains fixed.

Let the members, 1–2, 2–3, 3–4, ..., have the lengths, l_1, l_2, l_3, l_4, ..., before any stresses are present, and let these lengths become $l_1 + d\,l_1$, $l_2 + d\,l_2$, $l_3 + d\,l_3$, $l_4 + d\,l_4$, ..., under loading. Then, $\frac{d\,l_1}{l_1}$, $\frac{d\,l_2}{l_2}$, $\frac{d\,l_3}{l_3}$, ..., are the strains, positive if the members are increased in length. Let these strains be denoted by λ_1, λ_2, λ_3, ..., that is,

$$\lambda_1 = \frac{d\,l_1}{l_1};\ \lambda_2 = \frac{d\,l_2}{l_2};\ \lambda_3 = \frac{d\,l_3}{l_3};\ \text{etc.} \quad \ldots\ldots\ldots\ldots\ldots (61)$$

The initial positions of the joints are determined by their distances, (u_1, v_1), (u_2, v_2), (u_3, v_3), ..., from two axes at right angles to each other. These axes may be chosen anywhere, but must fulfill one condition, namely, if the u-axis is once chosen in direction, the v-axis must be situated in such a way, that a clockwise rotation through 90° of the u-axis will make it coincide with the v-axis (Fig. 20). The co-ordinate of a point with regard to an axis is considered positive if, looking along that axis in its positive

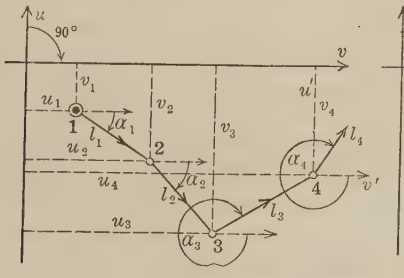

Fig. 20.

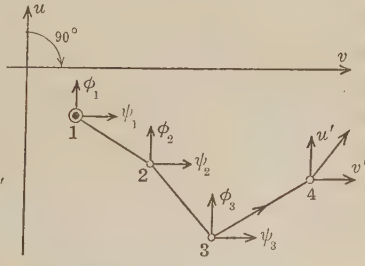

Fig. 21.

direction, the point lies on the right-hand side. Thus, all the co-ordinates in Fig. 20 are positive. The angles, α_1, α_2, α_3, ..., between the v-axis and the members, 1–2, 2–3, 3–4, ..., are the amounts of turning, in a clockwise direc-

tion, that would bring the v-axis into coincidence with the members, 1–2, 2–3, 3–4, ...

When $l_1, l_2, l_3, \ldots$, are changed by the small amounts, $d\,l_1, d\,l_2, d\,l_3, \ldots$, the angles, $\alpha_1, \alpha_2, \alpha_3, \ldots$, are changed by the corresponding small amounts, $d\,\alpha_1, d\,\alpha_2, d\,\alpha_3, \ldots$. Let,

$$\phi_1 = d\,\alpha_1,\ \phi_2 = d\,\alpha_2 - d\,\alpha_1,\ \phi_3 = d\,\alpha_3 - d\alpha_2 \ldots\ldots\ldots\ldots (62)$$

and, therefore,

$$d\,\alpha_1 = \phi,\ d\,\alpha_2 = \phi_1 + \phi_2,\ d\,\alpha_3 = \phi_1 + \phi_2 + \phi_3 \ldots\ldots\ldots\ldots (63)$$

The co-ordinates (u, v), of a joint, for example (u_4, v_4) of Joint (4), are expressed by,

$$\left.\begin{aligned} u_4 &= u_1 + l_1 \cos \alpha_1 + l_2 \cos \alpha_2 + l_3 \cos \alpha_3 = u_1 + \sum_1^3 l \cos \alpha \\ v_4 &= v_1 + l_1 \sin \alpha_1 + l_2 \sin \alpha_2 + l_3 \sin \alpha_3 = v_1 + \sum_1^3 l \sin \alpha \end{aligned}\right\} \ldots (64)$$

The small changes in the co-ordinates of Joint (4), due to the combined changes in the lengths of the members and the angles which the members make with the v-axis, are found by differentiating Equations (64). Keeping in mind that u_1 and v_1 are constant quantities,

$$\left.\begin{aligned} d\,u_4 &= \sum_1^3 d\,l \,.\, \cos \alpha - \sum_1^3 l \sin \alpha \,.\, d\,\alpha \\ d\,v_4 &= \sum_1^3 d\,l \,.\, \sin \alpha + \sum_1^3 l \cos \alpha \,.\, d\,\alpha \end{aligned}\right\} \ldots\ldots\ldots (65)$$

As $d\,l_1 = l_1\,\lambda_1$, from Equations (61),

$$\cos \alpha_1 = (u_2 - u_1) \,.\, l_1,$$

from Fig. 20, and,

$$\sin \alpha_2 = (v_2 - v_1) \,.\, l_1$$

the summations in Equations (65) become,

$$\left.\begin{aligned} \sum_1^3 d\,l \,.\, \cos \alpha &= (u_2 - u_1)\,\lambda_1 + (u_3 - u_2)\,\lambda_2 + (u_4 - u_3)\,\lambda_3 \\ -\sum_1^3 l \sin \alpha \,.\, d\,\alpha &= -(v_2 - v_1)\,d\,\alpha_1 - (v_3 - v_2)\,d\,\alpha_2 - (v_4 - v_3)\,d\,\alpha_3 \\ \sum_1^3 d\,l \,.\, \sin \alpha &= (v_2 - v_1)\,\lambda_1 + (v_3 - v_2)\,\lambda_2 + (v_4 - v_3)\,\lambda_3 \\ \sum_1^3 l \,.\, \cos \alpha \,.\, d\,\alpha &= (u_2 - u_1)\,d\,\alpha_1 + (u_3 - u_2)\,d\,\alpha_2 + (u_4 - u_3)\,d\,\alpha \end{aligned}\right\} (66)$$

Letting,

$$\psi_1 = \lambda_1, \psi_2 = \lambda_2 - \lambda_1,\ \psi_3 = \lambda_3 - \lambda_2$$

or,

$$\lambda_1 = \psi_1,\ \lambda_2 = \psi_1 + \psi_2,\ \lambda_3 = \psi_1 + \psi_2 + \psi_3 \ldots\ldots\ldots\ldots (67)$$

and using the relations expressed by Equations (62), and (63), Equations (66) take the following neat forms:

$$\left.\begin{aligned}
&\sum_1^3 d\,l\,.\cos\alpha = (u_4-u_1)\,\psi_1 + (u_4-u_2)\,\psi_2 + (u_4-u_3)\,\psi_3 = +u_{4\psi}, \text{ say}\\
-&\sum_1^3 l\sin\alpha\,.\,d\,\alpha = -(v_4-v_1)\,\phi_1 - (v_4-v_2)\,\phi_2 - (v_4-v_3)\,\phi_3 = -v_{4\phi}, \text{say}\\
&\sum_1^3 d\,l\,.\sin\alpha = (v_4-v_1)\,\psi_1 + (v_4-v_2)\,\psi_2 + (v_4-v_3)\,\psi_3 = +v_{4\psi}, \text{ say}\\
&\sum_1^3 l\cos\alpha\,.\,d\,\alpha = (u_4-u_1)\,\phi_1 + (u_4-u_2)\,\phi_2 + (u_4-u_3)\,\phi_3 = +u_{4\phi}, \text{ say}
\end{aligned}\right\} \quad (68)$$

Therefore, the changes in the co-ordinates of Joint (4), Equations (65), have the values:

$$\left.\begin{aligned} d\,u_4 &= u_{4\psi} - v_{4\phi}\\ d\,v_4 &= v_{4\psi} + u_{4\phi}\end{aligned}\right\} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (69)$$

Now, imagine Joint (1), Fig. (21), to be loaded with a positive weight, ϕ_1, parallel to the u-axis, and a positive weight, ψ_1, parallel to the v-axis; and Joint (2) to be loaded with a positive weight, ϕ_2, parallel to the u-axis, and a positive weight, ψ_2, parallel to the v-axis, etc. It will be seen that $u_{4\phi}$ of Equations (69) is the negative value of the sum of the moments of ϕ_1, ϕ_2, ϕ_3, about the axis, u', through Joint (4) parallel to the u-axis, while $v_{4\psi}$ is the negative of the sum of the moments of ψ_1, ψ_2, ψ_3, about the axis, v', through Joint (4) parallel to the v-axis. Further, if all the axes are turned in a clockwise direction through 90°, the u-axis and the u'-axis take the places and sense of the v-axis and the v'-axis, respectively, while the v-axis and the v'-axis take the places of the u-axis and the u'-axis, but are opposite to them in sense. Therefore, $u_{4\psi}$ of Equations (69) may be regarded as the negative of the sum of the moments of the ψ's about the new u'-axis, while $v_{4\phi}$ is the sum of the moments of the ϕ's, about the new v'-axis. The negative sign of $v_{4\phi}$ in the equation means that $-v_{4\phi}$ is the negative of the sum of the moments of the ϕ's, about the new v'-axis. Remembering that a positive weight on the right-hand side of an axis, and a negative weight on the left-hand side of an axis give positive moments, the argument becomes clear.

Therefore, considering two sets of positive weights, (ϕ_1 ϕ_2 ϕ_3) and (ψ_1 ψ_2 ψ_3), perpendicular to each other and acting at the Joints (1), (2), and (3), as shown in Fig. 21, the negative of $d\,v_4$ in Equations (69) may be obtained by taking the sum of the moments of the ϕ's about an axis, u', parallel to the u-axis, and those of the ψ's about an axis, v', parallel to the v-axis. If both axes are turned 90° in a clockwise direction, the negative of $d\,u_4$ in Equations (69) is the sum of the moments of the ϕ's, about the new v'-axis, and those of the ψ's, about the new u'-axis.

It is important to note that the argument is unaltered if, instead of Joint (4), the origin is any other point rigidly connected with the member, 3-4.

Small Movements of a Closed Chain.—For a closed chain, 1, 2, 3,..... n, 1 (Fig. 22), where Joint (1) is fixed in position and where the co-ordinates are as before, proceeding round the chain in the order 1, 2, 3, 4,.....n, 1, Equations (69) become:

$$\left.\begin{aligned} d\,u_n &= u_{n\psi} - v_{n\phi}\\ d\,v_n &= v_{n\psi} + u_{n\phi}\end{aligned}\right\} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (70)$$

for Joint (n), and the axes, u', v', now pass through Joint (n). It is possible, however, to go further and reach Joint (1). Considering Joint (1), not as the start but as the end of the route, Equations (69) become:

$$\left.\begin{aligned} d\,u_1 &= u_{1\psi} - v_{1\phi} \\ d\,v_1 &= v_{1\psi} + u_{1\phi} \end{aligned}\right\} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (71)$$

and the axes, u', v', now pass through Joint (1). As Joint (1), however, is fixed, $d\,u_1 = d\,v_1 = 0$ and Equations (71) are really.

$$\left.\begin{aligned} u_{1\psi} - v_{1\phi} &= 0 \\ v_{1\psi} + u_{1\phi} &= 0 \end{aligned}\right\} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (72)$$

If Joint (n) had been the terminus, it would have been necessary to consider all the ψ's, from ψ_1 to ψ_{n-1}, and all the ϕ's, from ϕ_1 to ϕ_{n-1}, in Equations (70). Proceeding to Joint (1) and obtaining Equations (72) adds ψ_n to the list of ψ's, and ϕ_n to the list of ϕ's. In other words, Equations (72) are true

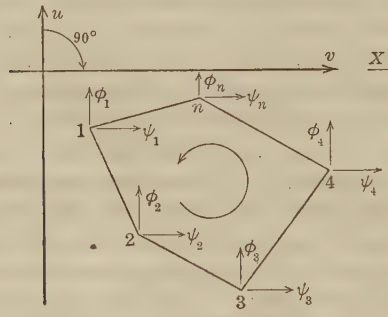

Fig. 22.

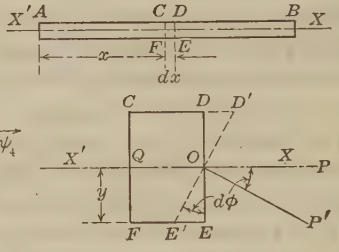

Fig. 23.

for all the weights, ψ and ϕ, of all the joints in the chain. Turning to Equations (62) and (67), it is evident that until now the ϕ's and ψ's have been taken as follows:

$$\left.\begin{aligned} \phi_1 &= d\,\alpha_1 && \text{and} && \psi_1 = \lambda_1 && \text{for Joint (1)} \\ \phi_2 &= d\,\alpha_2 - d\,\alpha_1 && \text{and} && \psi_2 = \lambda_2 - \lambda_1 && \text{for Joint (2)} \\ \phi_3 &= d\,\alpha_3 - d\,\alpha_2 && \text{and} && \psi_3 = \lambda_3 - \lambda_2 && \text{for Joint (3)} \\ &\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots \\ \phi_n &= d\,\alpha_n - d\,\alpha_{n-1} && \text{and} && \psi_n = \lambda_n - \lambda_{n-1} && \text{for Joint } (n) \end{aligned}\right\} \quad \ldots\ldots (73)$$

The moments of all the weights about the axes, u', v', through Joint (1) are under consideration; the moments of ϕ_1 and ψ_1, which act at Joint (1), are, therefore, zero. In other words, Equations (72) are not affected if either the axes, ϕ_1, ψ_1, are neglected or some other values substituted for ϕ_1 and ψ_1. A study of Equations (73) would suggest a completion of the cyclic order, by making,

$$\phi_1 = d\,\alpha_1 - d\,\alpha_n \text{ and } \psi_1 = \lambda_1 - \lambda_n$$

This gives two new relations, for on adding all the ϕ's,

$$\Sigma\,\phi = 0 \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (74)$$

and adding all the ψ's,

$$\Sigma\,\psi = 0 \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (75)$$

Now, the set of ψ's is a horizontal one, while the set of ϕ's is a vertical one, therefore, each set resolves itself into a couple and as the moment of a couple is constant, no matter where the axis is taken, the origin may be chosen anywhere. The direction of the u-axis is arbitrary, but, once chosen, it controls the position of the v-axis as that into which the u-axis falls when it is turned 90° clockwise. In that case, Equations (72) hold, as well as Equations (74) and (75). These are four linear relations that exist between the $2n$-quantities, ϕ and ψ. Hence, if $(2n\text{-}4)$ of the $2n$-quantities, ϕ and ψ, of a closed chain are known, the remaining four may be found.

A Beam Subjected to Bending.—Consider a beam, AB, Fig. 23, and let it be subjected to bending. Consider a small length, dx, of the beam, distant x from A, magnified as shown. Before bending, its shape is $C\,D\,E\,F$; after bending, it becomes $C\,D'\,E'\,F$, $C\,D$ suffering an elongation, $D\,D'$, and $E\,F$ a contraction, $E\,E'$, while the neutral axis remains unchanged. Imagine a perpendicular, $O\,P$, rigidly attached to the face, $D\,E$; that perpendicular will be carried to the position, $O\,P'$, when the beam is bent. The change in angle between $O\,P$ and $O\,P'$, $d\,\phi$, is what has been regarded as a weight in the foregoing discussion. If $d\,x$ becomes infinitesimally small, $Q\,O$ may be regarded as one of an infinite number of links, while the $d\,\phi$'s at their right-hand ends, O, become what are known as "elastic weights", and, as is well known,

$$d\,\phi = \frac{M_x \cdot d\,x}{E\,I} \qquad (76)$$

in which, M is the bending moment at the section, x.

A Beam Subjected to a Bending Moment at Each End.—Consider a beam, 1-2, Fig. 24. Let a counterclockwise (positive) moment, M_{12}, act at End (1); similarly, let a positive moment, M_{21}, act at End (2). The shape into which

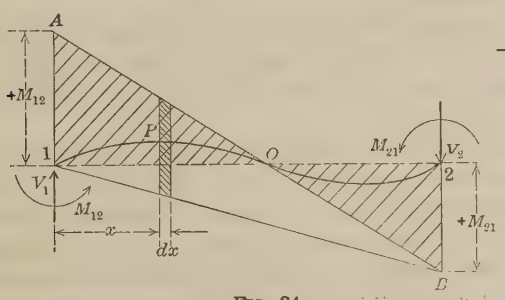

FIG. 24.

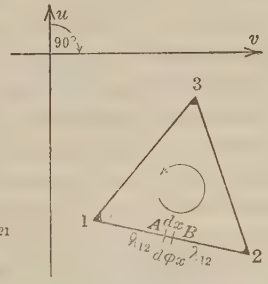

FIG. 25.

the beam is bent is somewhat as shown in the diagram. These moments induce a shear, V_1, upward at End (1), and a shear, V_2, downward at End (2). Taking moments about any point, P, distant x from End (1),

$$M_x = M_{12} - V_1 x$$

This proves that the variation of the moment is a linear one. Somewhere, however, between End (1) and End (2), there is a point of inflection, marked O, where the bending moment is zero. Hence, the bending moment diagram is as shown (shaded). Clearly, the bending moment area, $A\ O\ 1$, is positive,

while $B\ O\ 2$ is negative. If the portion, $1\ O\ B$, were added to $A\ O\ 1$, to make a positive area, $A\ B\ 1$, and also the same portion, $1\ O\ B$, to $B\ O\ 2$, to make a negative area, $1\ 2\ B$, these two newly found areas would have the same effect as the two original areas.

From Equation (76), however,

$$d\ \phi = \frac{M_x\ dx}{E\ I}$$

which represents the small bending moment area at x of width, $d\ x$. E is constant and the member is assumed to have a constant moment of inertia, I. Now, regard the positive bending moment area, $AB1$, as being replaced by all its small elastic weights, $d\ \phi$; these weights can themselves be replaced by their sum, acting at their centers of gravity, before treating them in any moment problem; but,

$$\phi_{12} = \int d\ \phi \text{ from End (1) to End (2)},$$

$$= \int_0^{l_{12}} \frac{M_x\ dx}{E\ I}$$

$$= + \frac{M_{12}\ l_{12}}{2\ E\ I}.$$

That is, it is permissible to replace all the elastic weights, $d\ \phi$, belonging to the positive area, $AB1$, by one elastic weight the value of which is ϕ_{12}, acting at the first "third" point from End (1) to End (2).

Similarly, all the elastic weights belonging to the negative area, $12B$, may be replaced by one elastic weight, $\phi_{21} = -\frac{M_{21}\ l_{12}}{2\ E\ I}$, acting at the second "third" point from End (1) to End (2).

Application of Elastic Weights to a Triangular Frame with Riveted Joints.—In the triangle, 1 2 3 (Fig. 25), the ends are riveted together so that the angle between the elastic lines of adjacent members at a joint, is constant under all conditions of loading.

Let the triangle be subjected to some loading, causing unit stresses, λ_{12}, in the member, 1-2, λ_{23} in the member, 2-3, and λ_{31} in the member, 3-1. Because of the riveted joints, some bending stresses will also be introduced throughout the frame. Consider End (1) fixed and u, v to be a pair of rectangular axes through any point in the plane of the frame; these axes are subject, however, to the condition that u must turn through 90° in a clockwise direction to coincide with v. It is assumed that anywhere in a member the direction of the displaced direct stress, due to the bending effect, deviates so little from that of the line joining the ends of the member, that the direction of the direct stress coincides with that line.

The triangle now becomes a closed chain, composed of an infinite number of links, dx, the joints, (1), (2), and (3), of the triangle serving as joints between adjacent links of two adjacent members. The riveted connections make this continuity possible. Following round the chain in a counterclockwise direction, take any one of the links of the member, 1-2, except the first,

such as AB, in Fig. 25. Joint (A) has a unit stress, λ_{12}, likewise Joint (B). Thus, in Equations (73), as applied to a closed chain, $\psi_B = 0$, while ϕ_B is the small elastic weight, $\frac{M_B\, dx}{E\, I}$, in which, M_B is the bending moment in the member at B, etc. If all the links but the first are taken, all the ψ's are zero while all the ϕ's are present.

In connection with the first link of the member, 2-3, the λ first met is the λ_{12}, while the second λ is λ_{23}. Therefore, at a point on the member, 2-3, adjacent to Joint (2), the ψ is $\lambda_{23} - \lambda_{12}$, and as the link is infinitesimally small, $\lambda_{23} - \lambda_{12}$ may be regarded as acting at Joint (2). Here, however, the ϕ is zero, as the end tangents to the elastic lines at Joint (2) are assumed to retain their relative positions. In considering the remaining links of the member, 2-3, all the ψ's are again zero, while the ϕ's are the elastic weights due to the bending of the member, 2-3.

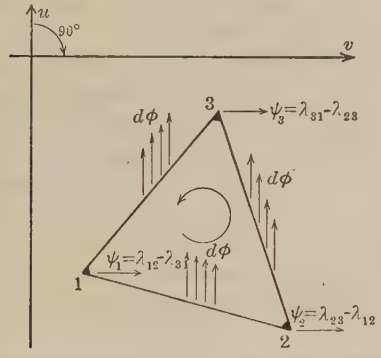

FIG. 26.

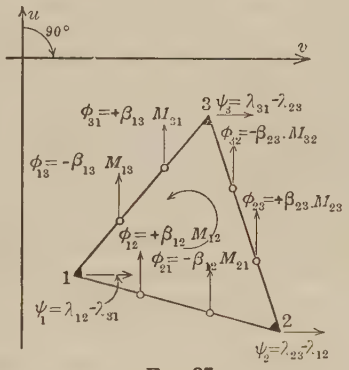

FIG. 27.

Arguments similar to the preceding, hold for Joints (3) and (1) and for the member, 1-3. Therefore (Fig. 26), it is required to account for only three ψ's, namely,

$$\left.\begin{aligned} \psi_1 &= \lambda_{12} - \lambda_{31} \text{ at Joint (1)} \\ \psi_2 &= \lambda_{23} - \lambda_{12} \text{ " " (2)} \\ \psi_3 &= \lambda_{31} - \lambda_{23} \text{ " " (3)} \end{aligned}\right\} \quad \ldots\ldots\ldots\ldots\ldots\ldots (77)$$

while there is an infinite number of $d\phi$'s along the members, 1-2, 2-3, and 3-1. It was proved in the preceding discussion that the infinite number of elastic weights, $d\phi$, of the member, 1-2, can be replaced by one elastic weight $= + \frac{M_{12}\, l_{12}}{2\, E\, I}$, acting at the first "third" point from the member, 1-2, and one elastic weight $= - \frac{M_{21}\, l_{12}}{2\, E\, I_{12}}$, acting at the second "third" point from the member, 1-2, in which $+ M_{12}$ is the bending moment at End (1), and $+ M_{21}$ is the bending moment at End (2), of the member, 1-2.

A similar argument holds for the members, 2-3 and 3-1. It is important to remember, that, as in the analysis of a closed chain, it is necessary to go

round the circuit in one direction. In Fig. 26, this direction is counterclockwise, hence, the first elastic weight met along the member, 1-2, is $+\frac{M_{12}\, l_{12}}{2\, E\, I_{12}}$, while the second is $-\frac{M_{21}\, l_{12}}{2\, E\, I_{12}}$, etc.

For convenience, let,

$$\beta = \frac{l}{2\, E\, I} \qquad (78)$$

The problem finally becomes a question of establishing enough relations between the ψ's and ϕ's, shown in Fig. 27. It is assumed that the direct stresses in the riveted frame are the same as if it were pin-connected; the λ's, and, therefore, the ψ's, are assumed to be known. There are six unknown bending moments, M, contained in the ϕ's. Assuming three of these bending moments to be known, moments of all the weights about three sets of axes, their origins not being collinear, will give three equations which will determine the remaining three unknown bending moments. The axes, of course, are chosen in such a way as to obtain the simplest relations.

Application of Elastic Weights to the Solution of the Moments in a Riveted Truss.—In the case of a riveted truss, made up of triangular elements and statically determinate, the joints being frictionless hinges, there are n joints, $(n\text{-}2)$ triangles, and $(2n\text{-}3)$ members. The number of bending moments to be determined is, therefore, $2\ (2n\text{-}3) = (4n\text{-}6)$, one of each end of each member.

The sum of the bending moments found at a joint is zero. As there are n joints, this gives n relations between the $(4n\text{-}6)$ bending moments. Therefore, there are needed $(4n\text{-}6) - n = 3\ (n\text{-}2)$ additional relations to solve the problem.

One assumes, as in the previous methods, that the direct or primary stresses in the members of the riveted truss are also those of a truss with frictionless hinges. Under any load, these stresses, therefore, are easily found, and, together with the dimensions of the truss, give the λ's and, therefore, the ψ's of Equations (77). The dimensions also determine the β's of Equation (78).

Each triangle is now considered by itself. The ϕ's belonging to the members of that triangle are placed at the third points, as in Fig. 27. The ψ's that arise from the stresses in the three members of the triangle, are placed at the vertices. It should be noted that the ϕ's of a side remain the same, in magnitude and sign, for the two triangles to which that side is common. Hence, after following round the first triangle in a clockwise direction, it is necessary, in order to preserve the signs of the ϕ's, to go round the next triangle in a counterclockwise direction, etc. The ψ's and ϕ's are regarded as weights. As each triangle is a closed chain, the sum of the bending moments of all the ϕ's about one axis, and the bending moments of all the ψ's about a perpendicular axis, is zero, the condition for the two axes being that the ϕ-axis must turn through 90° in a clockwise direction in order to coincide with the ψ-axis. Three such sets of axes are chosen for each triangle, to give the three relations required between the ϕ's and ψ's of each triangle. The three origins must not be collinear.

The method of procedure is first to assume the end moments of one of the two members making the first joint to be known. However, the sum of the bending moments at a joint is zero, therefore, that bending moment at the joint of the remaining member is also known. The remaining three bending moments of the first triangle are then solved by choosing three sets of axes. This being done in a definite way, as will be shown in the example, each additional equation will contain only one new unknown bending moment, all the others having already been expressed in the earlier equations. It must be borne in mind that as soon as the stage is reached where all but one of the bending moments around a joint are expressed in the equations already found, the relation, $\Sigma M = 0$, for the joint is introduced. It will be found that the $\Sigma M = 0$'s for the last two joints introduce no fresh bending moments; their use is found later. Call this whole set of equations, $(2n\text{-}6)$ in number, Set No. 1.

The next step is to express every M of Set No. 1 in terms of the M's found previously. Call this new set, Set No. 2.

It is then a matter of substitution to change Set No. 2 into Set No. 3, where every M is expressed in terms of the two M's assumed to be known at the start. Here, the last two equations of Set No. 1 are of value, for they are found to be two simultaneous linear equations with the two assumed M's which, therefore, are found. Substituting in Set No. 3 gives the values of all the M's from which to determine the secondary stresses. The method is easy to follow, as will be shown in an example.

7.—Mao's Methods

Fundamental Principles

The Fundamental Conception.—Quoting from Dr. Mao's thesis (28): Secondary stresses are fiber stresses, produced in the members, due to bending moments developed around the joints. There are many sources from which the moments are derived, but the principal one is the rigidity of connections. If M = the bending moment, I = the moment of inertia of the member, y = the distance from neutral axis to the fiber, the stress of which is required, and f = the secondary stress, then,

$$f = \frac{My}{I} = \frac{M}{S}$$

in which, S is the section modulus. Therefore,

$$M = S \cdot f \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (79)$$

In other words, if S is assumed as a force, and M is the moment it produces about a point, then the offset of the force from the point gives the value of the secondary stress.

Let AB be a member, connecting the Joints (A) and (B), and S its section modulus (Fig. 28). If S is assumed to be a force acting in this member, like the primary stress, it will produce moments at Joints (A) and (B) if its line of action is displaced from the axis of AB, and the offsets, f_a and f_b, will then be the stresses produced at Joints (A) and (B) (Equation (79)).

Particularly, if the moments about Joints (A) and (B) are those due to rigidity of joints, the offsets, f_a and f_b, will be the secondary stresses. The line of action of S will be called hereafter the "secondary stress line" or briefly "stress line", no confusion being caused thereby, as the primary stress line is not shown or is understood to be the axis of the member.

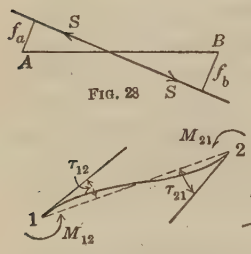

FIG. 28. FIG. 30.

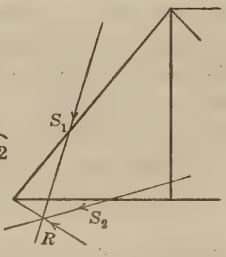

FIG. 29.

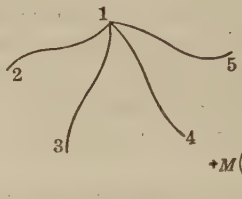

FIG. 31.

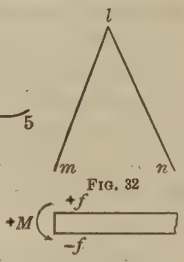

FIG. 32. FIG. 33.

It is now evident that the values of f depend only on the location of the stress line, S, while the moment, M, will also depend on its magnitude. As the magnitude of S is constant, being the section modulus, the position and direction of S, and, consequently, f, will depend solely on M.

Let this conception be extended to every member of the truss. There will then be as many stress lines as there are members. Each stress line will be displaced to an extent proportionate to the bending moments produced. To utilize this fact, by reversing the process, it is at once evident that, if the stress lines are located so as to satisfy various imposed conditions, the offsets of the stress lines will give directly the secondary stresses. This conception is fundamental.

The first condition, to which the various stress lines are subjected, is that the total resulting moments around every joint must be zero. (Eccentric moments are excluded here, but could be taken care of very readily.) Graphically, this means that, if a force diagram is drawn of all the stress lines in the truss, and an equilibrium polygon is likewise constructed on the truss diagram, these two polygons must, respectively, close. This, however, is impossible for the stress lines adopted previously, because, the values of S being constant, they could not be made to balance each other. Thus, in Fig. 29, the stress lines, S_1 and S_2, could not balance each other, unless they are on the same straight line, which is impossible. To overcome this difficulty, an external ideal force will be applied to the joint, with such magnitude and direction that the equilibrium is maintained around the joint. Thus, in Fig. 29, a force, R, may be introduced which will balance the forces, S_1 and S_2. In general, the magnitude and direction of R is equal to the resultant of the stress lines acting on the joint, but with opposite sense. It is important to notice that the position of R must be such that its line of action passes through the joint under consideration, so that there will be no external moment. In case of eccentric connections, the position of R may be adjusted so that its value and the offset from the joint will give the eccentric moment.

As a convenience in terminology, the term, "stress line", will be understood to be the internal secondary stress line, S, while the external force will be understood as the balancing force, R.

With the conceptions of S and R thus established, it is now possible to draw a force diagram around every joint from which to construct an equilibrium polygon. If these two polygons are made to close in any given case, the first condition, that the sum of internal moments must be zero around any joint, is everywhere satisfied. Further, from the condition that the total external moment is zero for all the joints of the truss, it may be inferred that both the force and equilibrium polygons of the external ideal forces, R, must, respectively, close.

The Fundamental Equation.—Dr. Mao's method for establishing this relation is unnecessarily complicated; an easier way, therefore, will be adopted as follows:

It has been shown (Fig. 5 and Equations (37) and (38)) that, if a member, 1-2, Fig. 30, is subjected to two positive bending moments (counterclockwise being the positive sense), M_{12} and M_{21}, at its ends, and if τ_{12} and τ_{21} are the angles between the end tangents and the chord at Member 1 and Member 2, respectively, then,

$$\tau_{12} = \frac{l_{12}}{6\,E\,I_{12}}\,(2\,M_{12} - M_{21})$$

and,

$$\tau_{21} = \frac{l_{12}}{2\,E\,I_{12}}\,(2\,M_{21} - M_{12})$$

Now, imagine a number of members, 1-2, 1-3, 1-4, 1-5, entering Joint (1), (Fig. 31),

$$\tau_{12} = \frac{L_{12}}{6\,E\,I_{12}}\,(2\,M_{12} - M_{21})$$

$$\tau_{13} = \frac{L_{13}}{6\,E\,I_{13}}\,(2\,M_{13} - M_{31})$$

Therefore,

$$\tau_{12} - \tau_{13} = \frac{L_{12}}{6\,E\,I_{12}}\,(2\,M_{12} - M_{21}) - \frac{L_{13}}{6\,E\,I_{13}}\,(2\,M_{13} - M_{31})$$

However, $\tau_{12} - \tau_{13} = \Delta\,\alpha_{213}$, this being the change in the angle, 213, under the loading, considering the joints as frictionless hinges. (See Fig. (6) and Equation (27)). Therefore,

$$L_{12}\left(\frac{2\,M_{12}}{I_{12}} - \frac{M_{21}}{I_{21}}\right) - L_{13}\left(\frac{2\,M_{13}}{I_{13}} - \frac{M_{31}}{I_{31}}\right) = 6\,E\,\Delta\,\alpha_{213}$$

or, by using Equation (79),

$$\frac{L_{12}}{y_{12}}\,(2\,f_{12} - f_{21}) - \frac{L_{13}}{y_{13}}\,(2\,f_{13} - f_{31}) = 6\,E\,.\,\Delta\,\alpha_{213}$$

In general, if two members, l-m and l-n, meet in a joint, Fig. 32, and if the order of consideration is in a counterclockwise direction,

$$\frac{L_{lm}}{y_{lm}}\,(2\,f_{lm} - f_{ml}) - \frac{L_{ln}}{y_{ln}}\,(2\,f_{ln} - f_{nl}) = 6\,E\,.\,\Delta\,\alpha_{mln}\,.\,.\,.\,.\,.\,.\,.\,.\,(80)$$

in which,

L = length of the member;
y = extreme fiber distance;
f_{lm} = secondary stress of the member, l-m, at the end, l; and
$\Delta\,\alpha_{nlm}$ = change of angle between the members, l-n and l-m.

This is Dr. Mao's "Fundamental Equation" which, he says, forms the basis for his "Theory of Deformation Contour" (see page 48).

Analytical Equations

In taking the bending moment as positive when it acts in a counterclockwise direction, it is seen that f, the stress of the fiber first met, is negative while that of the one passed over last in this counterclockwise route, is positive (Fig. 33).

On substituting U for $\frac{L}{y}$ and K for $6\,E\,.\,\Delta\,\alpha$, Equation (80) is changed to,

$$U_{lm}\,(2\,f_{lm} - f_{ml}) - U_{ln}\,(2\,f_{ln} - f_{nl}) = K_{mln}$$

or,

$$2\,f_{lm} - f_{ml} = \frac{U_{ln}}{U_{lm}}\,(2\,f_{ln} - f_{nl}) + \frac{K_{mln}}{U_{lm}} \qquad (81)$$

Now, let,

$$r_{lm} = 2\,f_{lm} - f_{ml}$$

and,

$$r_{ml} = 2\,f_{ml} - f_{lm} \qquad (82)$$

Equation (81) can then be written:

$$r_{lm} = \frac{U_{ln}}{U_{lm}}\,.\,r_{ln} + \frac{K_{mln}}{U_{lm}} \qquad (83)$$

From Equation (82),

$$r_{lm} = 3\,f_{ml} - 2\,r_{ml} \qquad (84)$$

and, also,

$$f_{ml} = \frac{1}{3}\,(2\,r_{ml} + r_{lm}) \qquad (85)$$

This shows that the value of r_{lm} may be obtained from the values of f and r at the other end of the member, without knowing the value of f_{lm}.

Graphical Constructions

Preliminary Considerations.—Quoting again from Dr. Mao's thesis:

Scales.—For graphical constructions, the scale of f is evidently dependent on that of $E\,\Delta\,\alpha$. From the fundamental Equation (81), it is seen that the scale of f is of the same dimensional degree as that of $\frac{K_{mln}}{U_{lm}}$, or of $\left(\frac{6\,E\,\Delta\,\alpha}{\frac{L}{y}}\right)_{lm}$.

As L is always expressed in feet and y in inches, L and y may be represented by the same unit, if $6\,E\,\Delta\,\alpha$ is changed into $\frac{E\,\Delta\,\alpha}{2}$. Hence, hereafter, K is to

be understood as $\frac{E \Delta \alpha}{2}$, with the understanding that y is expressed in inches, but represented as if it were in feet. As the values of $E \Delta \alpha$ are found from the primary stresses, by graphic or analytic methods, it is convenient to consider only one-half the primary stresses. In graphic methods, the scale of primary stresses may be made only one-half as large as that used for measuring the values of $E \Delta \alpha$. This will give the value of K directly.

The scale of S, the section modulus, used in constructing the force diagrams, may be any value independent of f, as it is only the direction that is required. The scale used for r must be the same as that for K or f.

Signs.—In the present work there are two instances where a conception of signs is necessary. One is rotational and the other is linear. The first applies to moments, angles, circular sections, and directions of contours, while the second applies to the stress lines, their offsets, representations of f and r, and the co-ordinates of variables. The rotational direction will always be considered positive if it is counterclockwise. For linear directions there are many considerations, but the principle is, with the exception of the stress lines, that if ab is the base of a straight line through a and b, with a as origin, the distance from a to any point, x, on ab, is positive, if x is laid off from a toward b, and negative, if away from b. That is, it is positive if it is between a and b, and negative if it is on the side of a away from b.

For stress lines the following convention is necessary: It has been shown that a positive moment is that, which will rotate a member in a counterclockwise direction; as the moment is represented by the product of f and S, the direction of S should be such that a counterclockwise moment would give a positive stress, f. For the sake of uniformity, all the stress lines, S, will be considered as compressive stresses in the members. Under this convention, if the stress lines in the members, 1-2 and 1-3, are as shown, Fig. 34, f_{12} and f_{21} will be negative (moment is clockwise about Joint (1) and also about Joint (2)), and f_{13} and f_{31} will be positive (moments about Joints (1) and (3) are counterclockwise). Hence, when the position of the stress line

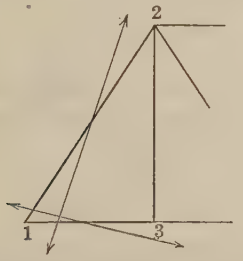

FIG. 34.

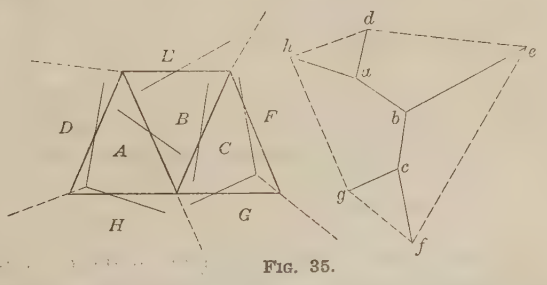

FIG. 35.

is known, both the sign and the magnitude of f are at once obtained. Further, by this convention, the force diagram of stress lines, S, assumes a definite form which tends to facilitate its construction. Consider the simple truss, as shown in Fig. 35. The letters, a, b, and c, in the force diagram correspond to the spaces, A, B, and C, of the truss diagram. It will be seen that the forces da, ab, bc, and cf, may be considered, for illustration, as the trunk of

a tree, while the forces, *ah*, *bc*, and *cg*, are its branches. This makes it easy to remember that all the stress lines in web members and end posts form the trunk of a tree, while those of the chord members form the spreading branches.

Truss Diagrams.—Two or three truss diagrams are necessary in the graphic methods presented in this paper. One of the diagrams will be used to record given information and to construct the values of K. The use of this diagram will be described, while the construction on the remaining diagrams will be considered subsequently.

The quantities, S, and primary stresses, in pounds per square inch, are first marked on all the members of the truss. The "y-circles" are then constructed. These are the circles, with radii equal to the y's of the members, drawn at one end of each member. Let L be the length of the member, in feet, and y, in inches (Fig. 36). At one end of the member draw a circle with radius equal to y, expressed in inches. The scale used is the same as that for L, which is in feet, the value of y being thus magnified twelve times. From the other end of the member draw a line tangent to this circle. This line will be known as the "U-line." To find the value of $\frac{K}{U} = \frac{\frac{K}{L}}{y}$, lay off a segment equal to K from the end of the member, from which the U-line is drawn. At the end of the segment, K, draw a circle, tangent to the U-line. The radius of this circle then gives the value required.

Changes of Angle.—The method of Ritter (page 9) is followed. The purely graphical construction of Mao is dangerous, because of possible mistakes in signs. All the triangles of the truss to be considered have a right angle; let P_{13}, P_{23}, and P_{12} (Fig. 37) be the stresses in the sides, 1-3, 2-3, and 1-2, respectively. These are drawn, to a certain scale, from the opposite vertices perpendicularly toward the sides, 1-3, 2-3, and 1-2, respectively.

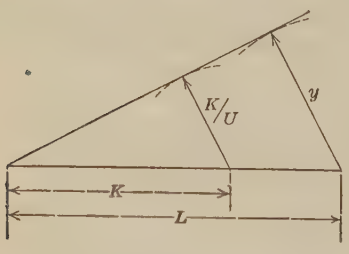

Fig. 36.

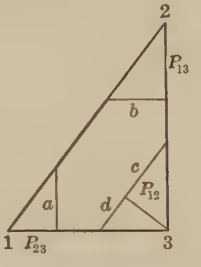

Fig. 37.

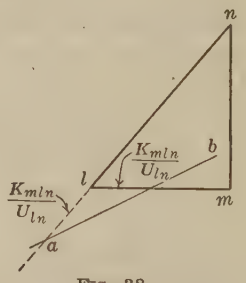

Fig. 38.

The lines, drawn through the ends of the P's and parallel to the sides opposite, give the quantities, a, b, c, and d. Now, the change of angle at Joint (2) is given by $(b\text{-}d)$. If P_{13} and P_{12} are both positive, it would be possible to superimpose d on b graphically, and thus mark off a length of line (positive if b is greater than d, and *vice versa*) that represents the change of angle, $\Delta\ \alpha_{123}$. It is readily seen that, with the P's differing in sign, such a process is extremely troublesome. It is wiser to introduce Mao's analytical method of

obtaining the changes of angle into his graphical solutions. This tabulation will be shown later.

Deformation and Property Lines.—Consider Equation (83):

$$r_{lm} = \frac{U_{ln}}{U_{lm}} \cdot r_{ln} + \frac{K_{mln}}{U_{lm}}$$

the quantities, $\left(\frac{U_{ln}}{U_{lm}}\right)$ and $\left(\frac{K_{mln}}{U_{lm}}\right)$, are constants under the particular loading of the truss, whereas r_{lm} and r_{ln} may be regarded as two unknowns. There is, therefore, a linear relation between them.

If lm and ln (Fig. 38) be the two axes (oblique in general), mark off $+\frac{K_{mln}}{U_{lm}}$ along lm and $-\frac{K_{mln}}{U_{lm}}$ along ln; this gives the straight line, a-b, which is called the "property line" of the triangle for the angle, mln. It is, in fact, the graph of Equation (83) on the two members considered as axes. There are three such deformation lines for every triangle. With regard to the convention of drawing them, it must be remembered that the U's are positive quantities, and the K's can be either positive or negative. If the K of an angle is positive, lay off a positive quantity along the member first met in a counterclockwise direction, and a negative quantity along the second member; if the K is negative, lay off a negative quantity along the first member and a positive quantity along the second.

Dr. Mao introduces what he terms the "property lines". From the fact that the sum of the three angles of a triangle remains constant, $\Sigma K = 0$ for every triangle. Using this, it can be shown analytically, that the three straight lines, through the vertices of a triangle and parallel to the corresponding deformation lines, are concurrent. Such a line would be:

$$r_{lm} = \frac{U_{ln}}{U_{lm}} \cdot r_{ln} \qquad (86)$$

the property line for the vertex, l, of the triangle, mln (Fig. 38). These lines may be regarded as the deformation lines for zero loading, when all the K's are zero. Use is made of this property to check the drawing of the deformation lines.

For the construction of the property and deformation lines, proceed as follows: Consider the truss diagram, Fig. 39, with all the U-lines drawn. Describe an arc of a circle with as large a radius as it is convenient to take and with Joint (1) as the center. Let this arc cut the member, 1-2, in a and the member, 1-3, in b. Draw perpendiculars to U_{12} and U_{13} from a and b, respectively. Let these be u_{12} and u_{13}.

In the second diagram, Fig. 40, lay off u_{13} from Joint (1) along the member, 1-3. Call the point, c. From c, lay off the length, $cd = u_{12}$, along the line through c, parallel to the member, 1-2. Join 1 to d. This is the property line for the angle $A1$, as $\frac{u_{12}}{u_{13}} = \frac{U_{12}}{U_{13}}$, fulfilling the requirements of Equation (86). This is repeated for every angle in the truss. In order to obtain the best results

the quantities, u_{12}, u_{13}, and, therefore, the radius of the circle, $a\,b$, must be as large as possible.

For the deformation lines, instead of any radius, select K_{312} to the scale of the f's, and describe an arc of a circle about 1 as the center. As the whole solution depends on the accuracy of locating these deformation lines, special care must be taken in this part of the work. Let the new points of intersection in Fig. 39 be a' and b', and the corresponding perpendiculars, u_{12}' and u_{13}'. Now, lay off u_{13}' along the member, 1-3, and u_{12}' along the member, 2-1, produced, if K_{312} is positive, whereas, lay off u_{13}' along the member, 3-1, produced, and u_{12}' along the member, 1-2, if K_{312} is negative. This is shown in Fig. 41 for convenience; in practice, the construction of the two sets of lines is on one diagram. A study of Equation (83) will prove that the line, *ef*, is the deformation line of the angle, *A*1. These deformation lines, now, must be parallel to the corresponding property lines, of which those belonging to a triangle must be concurrent.

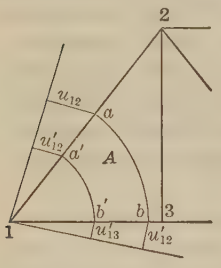

Fig. 39.

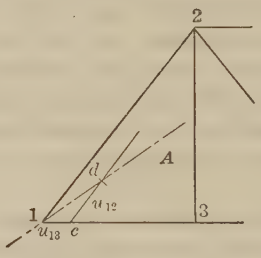

Fig. 40.

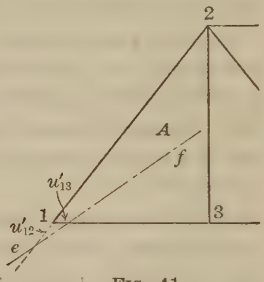

Fig. 41.

The Equilibrium Contour.—Quoting again from Dr. Mao's thesis: Under "Fundamental Conceptions" (page 40) (Fig. 29), it has been shown, that the stress lines, *S*, could be made to balance each other around any joint by the introduction of an ideal external force, *R*. In the process of construction, however, the conception of stress lines as there adopted is not convenient, as it would involve a different force diagram for each change of the stress lines, which is unavoidable in the graphical construction. A speedy method demands that one force diagram shall serve the whole process, that is, the direction of the stress lines is to be kept constant. This fixed direction of the stress lines is best chosen perpendicular to the axis of the member, for then the offset, $(= f)$, would be found along the axis of the member. For example, let S_{12}, Fig. 42, cut the member, 1-2, in *c*. The stress, f_{12}, is then equal to 1-*c*, positive if *c* is between 1 and 2, and negative if on the line, 2-1, produced. For the end, 2, the same force, S_{12}, should be shifted to a point the distance of which from the end, 2, gives the stress, f_{21}. By this modification, the direction of stress lines, *S*, is made constant for the members, and one force diagram is sufficient for different values of f at the same end of the same member. Here, these *S* lines are no longer the "Stress Lines", in the correct use of the term, but they will be known as the "Equilibrium Lines".

The direction of the equilibrium lines should be such, that they give a counterclockwise moment around the joint when the values of f are positive,

that is, when the lines cut the members somewhere between the joints. Thus, the direction of S_{12} should be upward, whether it is on the right-hand or the left-hand side of Joint (1). If on the left side of Joint (1), the moment is clockwise, and f is then negative.

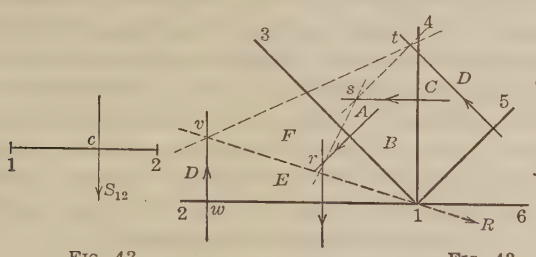

Fig. 42

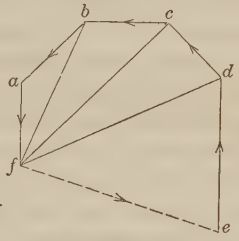

Fig. 43.

Consider the joint of a truss, as shown in Fig. 43. The force diagram is assumed to have been constructed. If the stresses in the members, 1-2, 1-3, 1-4, and 1-5, are known, the positions of the equilibrium lines are known. Then the moment of the member, 1-2, equals the force, *af*, multiplied by the perpendicular distance, f_{12}. If f_{12} is negative, it should be laid off on the side of 1 remote from 2, that is, along the member, 1-6. The closing line, *fe*, furnishes the external force, *R*, at the joint. The direction of the force is constant, and *R* may be drawn on the diagram as a part of the truss.

Suppose that the stress in the member, 1-6 ($= f_{16}$), is required, that is, the location of the force, *de*, the direction of which is upward, found by passing around the joint in a counterclockwise direction. In the force diagram, take *f* as the pole, and draw the rays, *fb*, *fc*, and *fd*. At the intersection, *r*, of the forces, *FA* and *AB*, draw a line parallel to *fb*, meeting the force, *BC*, at *s*. From *s* draw a line parallel to the ray, *fc*, meeting the force, *cd*, in *t*. From *t*, draw a line parallel to the ray, *fd*, meeting the force, *FE*, that is, *R*, at *v*. Then, the force, *DE*, must pass through *v*. Therefore, draw a perpendicular from *v* on the side, 1-6, and the distance, 1*w*, will give the value of f_{16}. It is negative here as it is on the side of 1, that is, remote from 6. Thus, it will be seen that only three lines are necessary for a joint of five members in order to determine the stress in the member, 1-6. For joints with a fewer number of members, only one or two lines are necessary. If there are eccentric connections at the joint, the eccentric moments, *M*, can be taken care of by displacing the force, *R*, a distance equal to $\frac{M}{R}$.

By a similar process the stress in any member may be found, if the stresses in all the other members meeting at the joint are known. The contour, formed by the force, *R*, and the equilibrium lines of the different members, will be known as the "Equilibrium Contour".

To cultivate speed and accuracy in drawing the force diagram for the equilibrium lines, the following method will be found useful. For a truss as shown, Fig. 44, first draw a line perpendicular to the member, 1-2, and measure $ha = S_{12}$. Then, from *a*, draw a line perpendicular to the member, 2-3, and

measure off $ab = S_{23}$. From b, draw a line perpendicular to the member, 2-5, and measure off $bc = S_{25}$. Continue for all the web members of the truss, until the points, e and f, are obtained. Only one-half the truss will be compared, as the other half will be symmetrical. From a, draw a line perpendicular to the member, 1-3, and measure off $ag = S_{13}$. The point, g, should be below a, so that the force, ag, will be downward. Similarly, from all the points, b, c, d, and e, draw lines perpendicular to the respective chord members, and measure off the segments, bk, cj, etc., equal to S_{35}, S_{24}, etc. All the values of the equilibrium lines are then constructed. Next, join the ends, l, j, h, g, etc., with the dotted lines shown. These will give the directions of the external forces, R, which are to be transferred to the truss diagram, as shown. Lastly, the rays, hb, hc, etc., are completed. They are the lines which join the left end of the external force, R, to the inner points of the diagram.

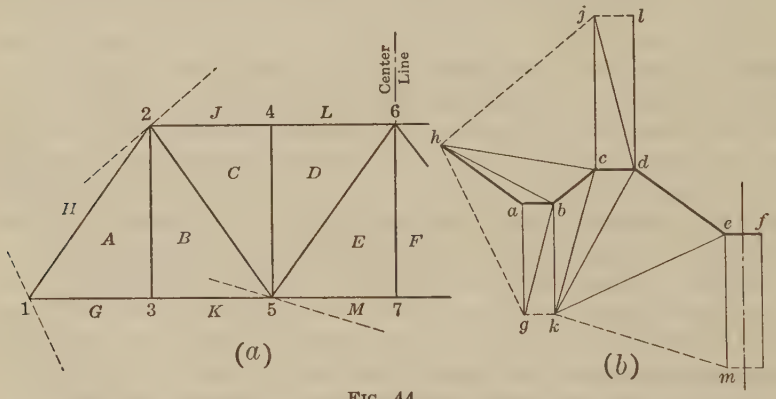

FIG. 44.

The Theory of Deformation Contour

Equation (83) applied to the deformation line of B-5, Fig. 44(a), shows that this deformation line is a graphical representation of the relation between r_{53} and r_{52}. Hence, if r_{53} is known, r_{52} is at once found; but knowing r_{52}, the deformation line, C-5, gives r_{54}, etc. In other words, if r_{53} is known, the deformation lines around Joint (5) permit all the other r's at Joint (5) to be found. This can be expressed analytically, by using Equation (83) in the following manner:

$$r_{52} = \frac{U_{53}}{U_{52}} \cdot r_{53} + \frac{K_{B5}}{U_{52}} \qquad (87)$$

$$r_{54} = \frac{U_{52}}{U_{54}} \cdot r_{52} + \frac{K_{C5}}{U_{54}}$$

and substituting from Equation (87):

$$r_{54} = \frac{U_{53}}{U_{54}} \cdot r_{53} + K_{B5} + \frac{K_{C5}}{U_{54}} \qquad (88)$$

$$r_{56} = \frac{U_{54}}{U_{56}} \cdot r_{54} + \frac{K_{D5}}{U_{56}}$$

and substituting from Equation (88):

$$r_{56} = \frac{U_{53}}{U_{56}} \cdot r_{53} + K_{B5} + K_{C5} + \frac{K_{D5}}{U_{56}} \quad \ldots\ldots\ldots\ldots\ldots\ldots (89)$$

$$r_{57} = \frac{U_{56}}{U_{57}} \cdot r_{56} + \frac{K_{E5}}{U_{57}}$$

and substituting from Equation (89):

$$r_{57} = \frac{U_{53}}{U_{57}} \cdot r_{53} + K_{B5} + K_{C5} + K_{D5} + \frac{K_{E5}}{U_{57}} \quad \ldots\ldots\ldots\ldots (90)$$

or,

$$r_{57} = a \cdot r_{53} + b \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (91)$$

where a and b are constants; similarly, for r_{52}, r_{54}, and r_{56}.

This is utilized in a simple yet elegant way. In Fig. 45, let 5-a represent r_{53} in magnitude and sign, as determined by earlier construction (assumed) similar to the one to follow.

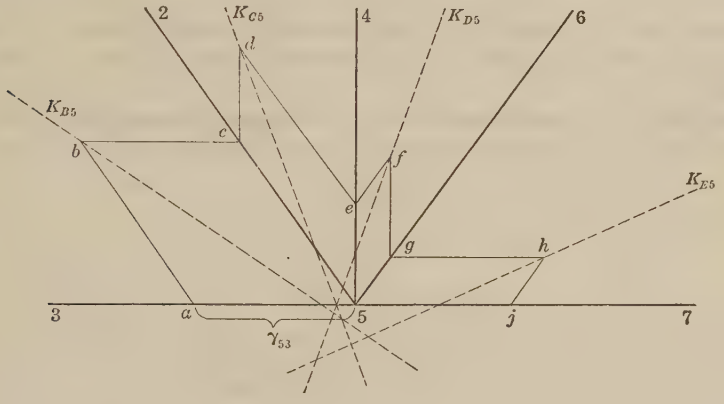

FIG. 45.

Draw ab parallel to the member, 5-2, to cut K_{B5} in b, K_{B5} being the deformation line of the angle, 5, in the triangle, B, and, therefore, supposed to be drawn by methods explained earlier. Draw bc through b parallel to the member, 5-3, to cut the member, 5-2, in c; 5-c is then r_{52}. Draw cd parallel to the member, 5-4, to cut K_{C5} in d, and then draw de parallel to the member, 5-2, to cut the member, 5-4, in e; 5-e is then r_{54}. Repeat this construction to find 5 $j = r_{57}$. This star-shaped diagram is the "deformation contour".

(Note that Dr. Mao introduces two 45° lines toward each other and downward from a and j. The whole diagram enclosed by these and the rays already drawn he calls the "deformation contour". These 45° lines are omitted from this investigation, as the writer fails to see their use; besides, the whole construction in an actual example becomes such a maze of lines that it is advisable to minimize the number.)

In order to use these deformation contours, Mao selects a certain member as the "reference" member for the deformation contour under consideration. It is always the member on the left of the joint. Thus, 5-3, Fig. 44(a), is the

reference member for Joint (5), 2-1 is the reference member for Joint (2), etc.

Suppose, the correct deformation contours for Joints (1) and (2) are known, that is, those contours that give the r's which, when substituted in Equation (85), will yield the desired secondary stresses, f. Substituting r_{12} and r_{21} in Equation (85),

$$f_{12} = \frac{1}{3}\,(2\,r_{12} + r_{21}) \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (92)$$

Now, because Joint (1) is in equilibrium under $S_{12} \cdot f_{12}$ and $S_{13} \cdot f_{13}$, the two moments at Joint (1),

$$f_{13} = -\frac{S_{12}}{S_{13}} \cdot f_{12} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (93)$$

Therefore, f_{13} and r_{13} are known, the former from Equation (93), and the latter from the assumed deformation contour of Joint (1); but r_{31} is related to f_{13} and r_{13} by Equation (84), therefore,

$$r_{31} = 3\,f_{13} - 2\,r_{13}.$$

By marking off r_{31} along 31, the deformation contour for Joint (3) may be completed in the same manner as in constructing the contour for Joint (5), Fig. 45.

To arrive at the correct value for r_{53}, the reference quantity for Joint (5), note that f_{31} and f_{32} are easily found, Equation (85), from,

$$f_{31} = \frac{1}{3}\,(2\,r_{31} + r_{13})$$

and,

$$f_{32} = \frac{1}{3}\,(2\,r_{32} + r_{23})$$

all the r's being known quantities. As $(\Sigma\, M)_3 = 0$, or,

$$S_{31} \cdot f_{31} + S_{32} \cdot f_{32} + S_{35} \cdot f_{35} = 0$$

or,

$$f_{35} = -\frac{1}{S_{35}}\,(S_{31} \cdot f_{31} + S_{32} \cdot f_{32})$$

The equilibrium polygon of the S's for Joint (3) gives the f_{35} in the quickest way. As r_{35} has already been determined,

$$r_{53} = 3\,f_{35} - 2\,r_{35}$$

from Equation (84), enabling the drawing of the deformation contour for Joint (5).

It is important to note that all this is possible because the relation between any r's and f's, or combinations of r's and f's, is a linear one.

Method of Successive Deduction

With regard to Mao's "Method of Successive Deduction", of which the writer has not carried out an actual example—this method depends on how closely a draftsman can guess the correct values of f_{12} and f_{21}. Suppose two values have been chosen. The foregoing analysis indicates the method of proceeding from joint to joint and fitting in all the deformation contours. When

the last two joints are reached, it will be found that the two relations, $\Sigma M = 0$, for these have not been used at all. After computing the values of ΣM (that is, $\Sigma S \,.\, f$), for these joints, making use of the r's found, in general, the resulting ΣM's will differ from zero. Now, assume two new values of f_{12} and f_{21}, repeat the preceding work and obtain a fresh set of values for the ΣM's of the last two joints; if these are nearer zero than the two from the first process, a judicious choice of the f_{12} and f_{21} will give a third approximation of ΣM that will be closer to zero than either of the former two solutions. This process may be continued until the ΣM's for the last two joints are as close to zero as desired. The final set of deformation contours will then give the required secondary stresses. It may be stated here that the element of chance, as in Ritter's method, is not attractive when there are straightforward methods available.

"Base" and "Vertex" Lines

In order to grasp the idea of Mao's "base" and "vertex" lines, it should be remembered that, by drawing the deformation contours for the r's and the equilibrium polygons for the f's, as already explained, linear relations are established between any desired set of r's, or f's, or combinations of them.

Consider the triangle, B, Fig. 44(a). Mao defines the member, 3-5, as its base (that member of the triangle, that lies in the boundary of the truss). Joint (2) is then its vertex; but Joint (2) is also a joint the reference contour of which is r_{21}. The base will carry the two contours, r_{35} and r_{53}.

Now,

$$r_{53} = a \,.\, r_{21} + b \,.\, r_{35} + c \ldots\ldots\ldots\ldots\ldots\ldots (94)$$

in which, a, b, and c are constants.

A proof of this is simple. Suppose, r_{21} and r_{35} to be known; r_{21} establishes a deformation contour round Joint (2), and r_{35} does the same for Joint (3), for, of course, the deformation contour round a joint can be done in either a clockwise or a counterclockwise manner. Now r_{23} and r_{32}, from these contours, give f_{32}, linear in r_{23} and r_{32} and, therefore, linear in r_{21} and r_{35}. Here one must take for granted something that will be proved later, namely, that r_{13} is found from r_{21} and r_{31}, also through a linear relation. Assuming this, as r_{31} and r_{35} are linearly connected, r_{13} is, therefore, a linear expression involving r_{35} and r_{21}. This then gives f_{31}, which is, in turn, only a linear function of r_{21} and r_{35}. Now, f_{35} is a linear function of f_{31} and f_{32} ($f \,.\, S = 0$), and, therefore, a linear function of r_{21} and r_{35}. Finally, $r_{53} = (3 f_{35} - 2 r_{35})$, and is, therefore, linear with respect to r_{21} and r_{35}.

Suppose, now, that a certain constant value, say, k, be assigned to r_{21}. The relationship, then, between r_{53} and r_{35} will be graphically represented by a straight line. Equation (94) becomes:

$$r_{53} = b \,.\, r_{35} + (c + a\,k) \ldots\ldots\ldots\ldots\ldots\ldots (95)$$

in which, $(c + a\,k)$ is a constant. If, now, some value is given to r_{35}, the corresponding value of r_{53} is at once determined.

Lay out these corresponding values along the member, 3-5, as shown in Fig. (46). Through the end points, p and q, draw two lines at 45° to meet in P.

$$x = y + r_{35}$$

and,

$$y = \frac{1}{2}(d - r_{35} - r_{53}) \ldots\ldots\ldots\ldots\ldots\ldots\ldots (96)$$

These relations are evident from a study of Fig. 46. Eliminating r_{35} and r_{53} from Equations (95) and (96),

$$y = \frac{(b + 1)}{(b - 1)} \cdot x + \frac{(a\,k + c - d)}{(b - 1)} \ldots\ldots\ldots\ldots\ldots\ldots (97)$$

This proves that, for a constant value of r_{21}, P lies on some definite straight line. If r_{21} be given the constant value of zero, the locus of P is called the "base line".

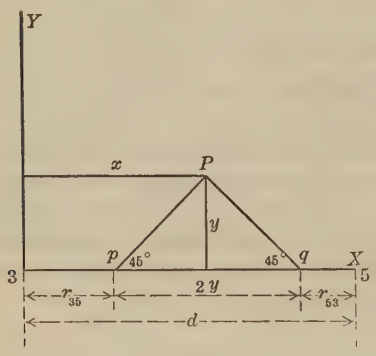

FIG. 46.

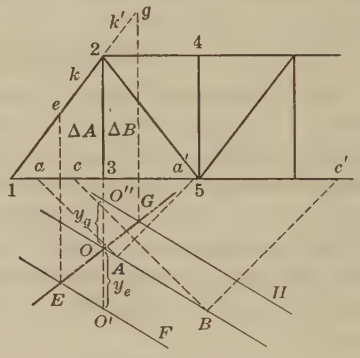

FIG. 47.

It is at once evident from Equation (97) that every value of r_{21} defines a certain straight line, but as this value of r_{21} is incorporated in the constant term of Equation (97) all these lines are parallel to the "base line".

Let $O\,A\,B$ (Fig. 47) be the base line of $\Delta\,B$. In order to obtain this, r_{21} is assumed to be zero, while two sets of corresponding values of r_{35} and r_{53} are determined. The graphical method of doing this will be shown later.

Let two such sets be ($3a$, $5a'$) and ($3c$, $5c'$). Lines at 45° through a and a' give A, and through c and c' determine B. Let the point of intersection of AB and the member, 2-3, be O. Let $E\,F$ be the line that gives the relationship between r_{35} and r_{53} for a value of, say, $r_{21} = 2e = k$, and let $G\,H$ be that when, say, $r_{21} = 2g = k'$. Draw the perpendiculars, $e\,E$, $g\,G$ to the member, 3-5, and let these cut $E\,F$ and $G\,H$ in E and G, respectively. Join $E\,O$ and $O\,G$. The horizontal distances from E and G to the member, 2-3, are proportional to k and k'. Now, 3-O, 3-O', and 3-O'' are the y-intercepts for the lines, $A\,B$, $E\,F$, and $G.\ H$, respectively, and are, therefore, from Equation (97), respectively, equal to:

$$\frac{c - d}{b - 1},\ \frac{a\,k + c - d}{b - 1},\ \text{and}\ \frac{a\,k' + c - d}{b - 1}.$$

Hence,

$$O\,O' = \frac{a\,k + c - d}{b - 1} - \frac{c - d}{b - 1} = \frac{a\,k}{b - 1},$$

and,

$$O\,O'' = \frac{a\,k'}{b - 1}.$$

The algebraic signs are correct. Therefore, the ratio of $O\,O'$ to $O\,O''$ is $\frac{k}{k'}$. Further, as the angles, $O\,O'\,E$ and $O\,O''\,G$, are equal, because $G\,H$ and $E\,F$ are parallel, the two triangles, $O\,O'\,E$ and $O\,O''G$, are similar. The angles, $E\,O\,O'$ and $G\,O\,O''$, are, therefore, equal, and, hence, E, O, and G are collinear.

If any other value for r_{21} be chosen, the perpendicular from the end point to the "base", 3-5, will cut the corresponding line of the parallel family in a point on the straight line, $E\,G$. This is Dr. Mao's "vertex line".

(Note that it is now possible to verify the assumption used in the proof for Equation (94). The base and vertex lines of $\Delta\ A$ may be obtained in exactly the same way as for $\Delta\ B$. This means that the relationship between r_{21}, r_{13}, and r_{31} is linear, just as that for r_{21}, r_{35}, and r_{53}, the quantity, r_{21}, being the reference contour in each case. This justifies the statement that f_{31} is a linear function in r_{21} and r_{35}, etc.)

Construction of Base and Vertex Lines

As the base line is a straight line, two points will determine it completely. A splendid check, however, can be introduced here, for if three points are found independently of each other, and are collinear, there is little chance of the base line being wrong. Hence, throughout the work of locating base lines, three points are to be determined for every line.

In determining a vertex line, its accompanying base line having already been found, note that one point on the vertex line is the point of intersection of the base line and the perpendicular from the vertex (see Fig. 47). It remains, therefore, to find two more points, which must be collinear with that on the base line.

Let the base and vertex lines for a truss, shown in Fig. 44(a), be required. This is a Warren truss with verticals, but the method is applicable to all kinds of trusses, the only difference being found in the order of procedure, which is governed by the number of members meeting at the joints. The base of a triangle is always chosen as the member that forms the outline of the truss.

Base and Vertex Lines for $\Delta\ A$.—Either the member, 1-2, or the member, 1-3, may be chosen as the base, as each is part of the outline of the truss. Although only one set of base and vertex lines is necessary for the solution of the problem, it offers a neat check to introduce both sets; this will be explained in the example.

Member 1-3 as Base.—As the vertex of $\Delta\ A$ is Joint (2), the base line is obtained by assuming r_{21} equal to zero, as the member, 2-1, is the reference member for Joint (2).

Some arbitrary value is now assigned to r_{13}, and the deformation contour for Joint (1) completed. This gives the value of r_{12}. As $2\,r_{12} + r_{21} = 3\,f_{12}$ (see Equation (85)), and $r_{21} = 0$ here, let the force, S_{12}, act perpendicularly to

the member, 1-2, at a distance, $2\,r_{12}$, from it. Through the point of intersection of S_{12} and R_1 (the line of action of which has already been determined from the force polygon), draw a line perpendicular to the member, 1-3; the distance from Joint (1) along the member, 1-3, thus found gives the value $3\,f_{13}$; but $r_{31} = 3\,f_{13} - 2\,r_{13}$ (see Equation (84)). Then r_{31} is laid off from Joint (3) along the member, 3-1, care being taken that, if it is negative, it must be measured along the member, 1-3, produced. A line, at 45° to the member, 1-3, and downward to the right, is now drawn through the end of r_{13}, and a line, at 45° to the member, 1-3, downward but toward the left, is drawn through the end of r_{31}; the point of intersection is one of the points on the required base line.

The process is twice repeated, that is, r_{21} remains zero while two more arbitrary values are given to r_{13}. This gives two more points for the base line. If care has been taken with regard to the signs, and the draftsmanship has been accurate, these three points will be found to be collinear, determining the base line for ΔA with the member, 1-3, as base.

By producing the member, 2-3, to cut the base line just found, the first of the three points for the required vertex line is obtained. To get a second point, assume a fairly large value for r_{21} (no longer zero, as for the case of the base line), and some arbitrary value for r_{13}. Using the latter, construct the deformation contour for Joint (1), to find r_{12}. As $3\,f_{12} = 2\,r_{12} + r_{21}$, it is possible to complete the equilibrium polygon round Joint (1), giving $3\,f_{13}$. Now $r_{31} = 3\,f_{13} - 2\,r_{13}$. The two corresponding values of r_{13} and r_{31}, therefore, are known, and by drawing the two 45° lines downward toward each other through the ends of r_{13} and r_{31}, their point of intersection is a point on the straight line parallel to the base line already found. Draw this parallel line; where it cuts the vertical through the end of r_{21}, is one of the points on the required vertex line. Repeat this process with a different r_{21}, fairly large and preferably with a sign different from that already used, this greatly improves the accuracy. The three points should be collinear, giving the required vertex line for ΔA with the member, 1-3, as base.

(Note that Dr. Mao draws his equilibrium polygons with the offsets equal to the values of the f's. It will be noticed that in changing from r's to f's and *vice versa* (see Equation (85)), it is most convenient to work with three times the f-values. An equilibrium polygon around a joint is magnified, therefore, just three times, and not only is time saved, but great accuracy is obtained. Throughout this investigation, the equilibrium polygons are to be understood as being drawn with the $3\,f$-values.)

Member 1-2 as Base.—The vertex is now Joint (3) which has the member, 3-1, for reference member. To obtain the base line, assume r_{31} to be zero, and r_{12} as some arbitrary value. With this r_{12} the deformation contour for Joint (1) is constructed. Now $3\,f_{13} = 2\,r_{13} + r_{31}$, and as $r_{31} = 0$, the equilibrium polygon for Joint (1) is completed by starting with S_{13}, acting at the end of $3\,f_{13} = 2\,r_{13}$. This construction then gives $3\,f_{12}$, but as r_{12} was assumed at the start, the corresponding r_{21} results from $r_{21} = 3\,f_{12} - 2\,r_{12}$. Drawing the 45° lines (to the member, 1-2, in this case) through the ends of r_{12} and r_{21}, deter-

mines the first point on the base line of ΔA, Vertex (3). This process, repeated twice for two new and arbitrary values of r_{12}, gives the two additional points. If the three points are found to be collinear, it is safe to say that the base line has been determined.

To determine the vertex line, assume a fairly large value of r_{31} and use it in conjunction with an arbitrarily chosen r_{12} to obtain the corresponding r_{21} eventually. The difference between this and the analysis for the base line is that the r_{31} in $3 f_{13} = 2 r_{13} + r_{31}$ is no longer zero. The two 45° lines through the ends of r_{12} and r_{21} now determine the point through which a line is drawn parallel to the base line already found. The perpendicular from the end of r_{31} to the base, 1-2, intersects this parallel in a point on the required vertex line. The point where the perpendicular from the Vertex (3) cuts the base line is, of course, another point on the vertex line. A conclusive check is to take another fairly large value of r_{31} and proceed to find a third point, and if this is collinear with the two already found, the vertex line is located.

Base and Vertex Lines for ΔB.—The base for ΔB is the member, 3-5, and the vertex, Joint (2), so that the base line is obtained by making $r_{21} = 0$, the deformation contour for which is drawn. As before, assume a value for r_{35} and find the corresponding value for r_{53}; these two values will determine a point on the base line. On account of the greater number of members entering Joint (3), the process is a little more complicated than for ΔA, but the principle is the same.

For the assumed value of r_{35}, construct a deformation contour for Joint (3), giving r_{32} and r_{31}. Now, as $r_{21} = 0$, the value of r_{13} is found by drawing a 45° line down to the left from the end of r_{31} to the base line of ΔA, Vertex (2), and then a 45° line from this point of intersection to cut the member, 1-3, giving r_{13}. Of all the r's connected with the members entering Joint (3), r_{53} is now the only one unknown. To determine it, the equilibrium polygon for Joint (3) is drawn by making S_{31} act perpendicularly to the member, 3-1, at a distance $3 f_{31} = 2 r_{31} + r_{13}$ from Joint (3) along the member, 3-1, and by making S_{32} act perpendicularly to the member, 3-2, at a distance $3 f_{32} = 2 r_{32} + r_{23}$ from Joint (3) along the member, 3-2; these, together with the resultant R_3, determine the line of action of S_{35}, giving $3 f_{35} = 2 r_{35} + r_{53}$. Hence, $r_{53} = 3 f_{35} - 2 r_{35}$, and the point on the base line of ΔB is found. Two more points are determined, and if the three are collinear the construction for the base line is correct.

The vertex line is determined by assuming fairly large values for r_{21}. These values give certain deformation contours for Joint (2), while they also belong to definite lines parallel to the base line of ΔA, Vertex (2). These parallel lines are found by drawing perpendiculars from the ends of r_{21} to cut the vertex line of ΔA, the parallel lines passing through the points just found. It is these parallel lines that must now be utilized to obtain the values of r_{13} from those of r_{31}, which have themselves come from arbitrary values of r_{35}. The equilibrium polygon for Joint (3) follows, and, hence, r_{53} is determined. The points, determined from corresponding values of r_{35} and r_{53}, are on lines parallel to the base line of ΔB. The points where these parallels cut the verticals from the respective r_{21}'s are on the vertex line required. If two such

points and the point where the perpendicular from Vertex (2) to the base, 3-5, cuts the base line of ΔB, are collinear, the vertex line for ΔB is determined.

Base and Vertex Lines for ΔC.—The base for ΔC is the member, 2-4, and the vertex, Joint (5). The base line, therefore, is obtained by making $r_{53} = 0$ (5-3 being the reference member) and assuming three different values for r_{24}, from which three corresponding values of r_{42} are obtained. In each of these cases r_{53} is zero.

To arrive at a value of r_{42} from a given r_{24} and $r_{53} = 0$, follow the same principle as before. A glance at Fig. 44(a) will show that, in order to get to r_{42}, $3f_{25}$, $3f_{23}$, and $3f_{21}$ must first be obtained, with which to draw an equilibrium polygon for Joint (2) that will give $3f_{24}$; then only is $r_{24} = 3f_{24} - 2r_{24}$ obtained. The deformation contour around Joint (2) for the r_{24} under consideration, and the deformation contour around Joint (3) for $r_{53} = 0$, give r_{25} and r_{52}, respectively. Then, $3f_{25} = 2r_{25} + r_{52}$. The value of r_{21}, from the former contour, also determines the parallels to the base lines of ΔA and ΔB, 2-1 being the reference member for both. A 45° line, from Joint (5) to the parallel to the base line of ΔB, gives the point from which to draw upward at 45° to obtain r_{35}; this is because $r_{53} = 0$. Use this value of r_{35} for a deformation contour for Joint (3), and with the r_{31} thus found and the parallel to the base line of ΔA, obtain r_{13}. This gives the deformation contour around Joint (1). The quantities, $3f_{25} = 2r_{25} + r_{52}$, $3f_{23} = 2r_{23} + r_{32}$, and $3f_{21} = 2r_{21} + r_{12}$, are now known, and the problem is solved.

The vertex line is obtained by assuming for r_{53} two values of different magnitude, preferably of different sign. These values give two deformation contours around Joint (5). By giving an arbitrary value to r_{24}, it is possible to proceed exactly as before to get the corresponding r_{42}, the only point to notice being that r_{52} is not zero now, so that the 45° lines must start, not from Joint (5), but from the end of r_{53}. The third point on the vertex line is where the perpendicular from Vertex (5) to the base, 2-4, cuts the base line of ΔC.

(Note that all the 45° lines are drawn away from the truss, so that the base and vertex lines for ΔC, ΔD, ΔG, and ΔH will be situated somewhere above the truss diagram, while those of ΔA, with Joint (3) as its vertex, lie to the left, those of ΔJ, with Joint (11) as vertex, to the right, and the remainder below the truss diagram. This is done to keep the drawing as clear as possible.)

Solution of Problem by Deformation Contour

The solution depends on the determination of all the base and vertex lines of all the triangles. The foregoing explanation appears to be difficult because it is long; this seems to be unavoidable. The writer found that, by merely reading Dr. Mao's thesis, his method seemed very difficult, but after going through the computations of an actual example the whole principle became exceedingly clear and simple. Any one who is eager to know Mao's work thoroughly is strongly advised, therefore, to work out a simple example; if time will not permit, a neat freehand sketch, accompanying the reading, will serve the purpose.

The base and vertex lines for the triangles, Fig. 44(*a*), are found in the following order, the vertex line of a triangle being determined immediately after the base line of the triangle in question: ΔA with either Joint (2) or Joint (3) as vertex, the order of procedure being immaterial; ΔB with Joint (2) as vertex; ΔC with Joint (5) as vertex; ΔD with Joint (5) as vertex, etc.

When this stage is reached, it becomes evident that ΔJ has the member, 10-12, in the outline of the truss, but instead of obtaining only one set of base and vertex lines with the vertex at Joint (11), two are obtained, one by considering the equilibrium of Joint (12), and the second that of Joint (10). It is on this property that the solution of the whole problem depends. It is the same idea that underlies the method of Müller-Breslau and that of Mohr (by elastic weights), where the two last joints give two equations wherewith to solve the two values assumed in the beginning.

Assume that the two sets of base and vertex lines of ΔJ, Vertex (11), are drawn and, of course, all the preceding ones. The reference member for ΔJ, Vertex (11), is 11-9. Assume any arbitrary value for $r_{11\cdot9}$. A perpendicular, from the end point of $r_{11\cdot9}$ to the member, 12-10, will cut the two vertex lines of the respective sets for ΔJ, Vertex (11), in two points, through which parallels to the respective base lines are then drawn. These parallels determine a point, most important inasmuch as it is common to the two sets. Proceed to draw 45° lines to the member, 10-12, from this point. Two values are determined, namely, $r_{10\cdot12}$ and $r_{12\cdot10}$. Complete the deformation contours round Joints (10) and (12). The value of $r_{10\cdot8}$ found will enable the determination of a parallel to the base line of ΔJ, Vertex 10 (10-8 is the reference member in this case); this parallel must be used in conjunction with $r_{12\cdot11}$, from Contour (12), to obtain $r_{11\cdot12}$. Complete the deformation contour for Joint (11). The value of $r_{11\cdot9}$ thus found will, in general, be quite different from that assumed at the start. The object is to obtain an exact coincidence. A second value of $r_{11\cdot9}$ is judiciously assumed; it is advisable that this value approximate the one found in the process just described. The above procedure is then repeated. It will be found that the resultant value of $r_{11\cdot9}$ will come fairly close to that assumed. This process of choosing $r_{11\cdot9}$ and drawing is repeated a few times; after the fourth attempt, it is customary to check the value of $r_{11\cdot9}$ last chosen.

Assume that the correct $r_{11\cdot9}$, with the attendant deformation contours round Joints (12), (11), and (10), are now known. Draw the perpendicular from the end of $r_{10\cdot8}$ to cut the vertex line of ΔI; through this point, draw a line parallel to the base line of ΔI. Use this parallel to determine $r_{9\cdot11}$ from $r_{11\cdot9}$. Complete the deformation contour of Joint (9) giving $r_{9\cdot7}$. This is now the reference contour for ΔH and ΔG. Using it, determine $r_{8\cdot10}$ from $r_{10\cdot8}$, and complete the deformation contour for Joint (8). This process is continued for all the joints. ΔA will have been reached and all the deformation contours of all the joints will have been drawn, without having made use of the base and vertex lines of ΔA, Vertex (3). Their usefulness lies in the following: Draw a perpendicular to the member, 1-2, from the

end of r_{31}, this being the reference contour. This line cuts the vertex line in a point through which a line is now drawn parallel to the base line. Draw lines at 45° to the member, 1-2, from the ends of r_{21} and r_{12}. If the work has been accurate, these 45° lines must intersect each other on the parallel line just drawn.

Consider, for example, Joint (6). The r's of all the members entering Joint (6) have been found. Lay off from Joint (6) the quantities, $(2\ r_{68} + r_{86})$, $(2\ r_{69} + r_{96})$, $(2\ r_{67} + r_{76})$, $(2\ r_{65} + r_{56})$, and $(2\ r_{64} + r_{46})$, along the members, 6-8, 6-9, 6-7, 6-5, and 6-4, respectively. These are now the 3 f's of the members. The resultant, R_6, of the forces, S_{68}, S_{69}, S_{67}, S_{65}, and S_{64}, is known in magnitude and direction from the force polygon, while its point of application is Joint (6). Draw the equilibrium polygon, considering everything known but the point of application of S_{64}. This will give the quantity, 3 f_{64}, which, together with the quantities, 3 f_{68}, 3 f_{69}, 3 f_{67}, and 3 f_{65}, will cause equilibrium round Joint (6), that is, $(\Sigma\ S\ .\ 3\ f)_6 = 0$. If the work has been exact this value, 3 f_{64}, will correspond exactly with 3 f_{64} found from the deformation contours, namely, $2\ r_{64} + r_{46}$; the closeness in agreement will be a measure of the accuracy of the drawing. Repeat this for all the joints. If the agreement is good in all cases, the values of the 3 *f's* may be considered to be correct. A third of each of these values gives the corresponding secondary stress.

Analytical Solution by the Scientific Arrangement of Computations

Introduction.—This method is simply the application of Equations (81) to (85), together with the equations found at the joints, namely, $\Sigma\ M = 0$. Its underlying principles, therefore, are easy. The difficulty is that, in common with the methods of deformation contour and successive deduction, it needs a long explanation, accompanied by a diagram. The method is indeed very much like that of Müller-Breslau; Mao also assumes two quantities known at the start, and using these throughout the process, finally arrives at two simultaneous equations the solution of which determines the two assumed quantities. The assumed quantities in this method are the secondary stresses of the first member of the truss.

Mao uses two truss diagrams. He has an ingenious device for determining the changes of the angle, $\Delta\ \alpha$, on the first diagram. On the second diagram, he places a number of skeleton tables which must be filled out in a certain definite way; each place in every table has a definite significance and seldom is any quantity repeated.

A point that must be emphasized again is this: If the two assumed secondary stresses of the first member are x and y, with reference to Equations (81) to (85) and the $\Sigma\ M = 0$ equations, that is, $\Sigma\ S\ .\ f = 0$ equations (see Equation (79)), it is to be noted that every relation to be established during the analysis will be one of the first degree in x and y.

Application.—As the theory has been proved, the method will be illustrated by actually applying it to a simple case. Consider a truss composed of two triangles; the solution of this truss embodies all the elements found in one with

a greater number of triangular elements. Further, as most trusses are composed of right-angled triangles, Mao's method for finding the changes of angle will be given for right-angled triangles only. It is really Ritter's method (see page 9).

In Fig. 48 are two diagrams, representing a truss composed of two triangles, A and B. On Fig. 48 (a), write out the lengths, L, in feet, moments of inertia, I, in inch units, and the extreme fiber distances, y, in inches, as shown. These are obtained from the dimensions of the truss. Now imagine the truss to be loaded, giving the unit stresses, P, in pounds per square inch, which are also written on the members. Obtain also, from the dimensions, the half values of the co-tangents of α and β.

In each of the triangles, A and B, Fig. 48(a), make a table as shown, observing the proper positions for the various values. The quantities at the three ends are K_{A1}, K_{A2}, and K_{A3}. These K's are the half values of the product of the modulus of elasticity and the changes of the angle, $\Delta\alpha$. (Equation (81); see, also, "Preliminary Considerations," page 42.) A comparison between this method, and "The Changes of Angle" as discussed on page 44, will show that the method is legitimate. K_{A1} is the change of Angle (1) in Triangle (A), and is found at the end of the A-table, nearest to Joint (1). Similarly, for all the other K's.

In Fig. 48(b), directly below Joints (1), (3), and (4), and directly above Joint (2), place the ΣM- and the ΣK-tables as shown. In the ΣK-table, include all the members that meet in the joint except the first. This comprises the members, 3-2 and 3-4, for Joint (3). The first member of a joint in the bottom chord is that which is first met on entering the truss in a clockwise direction round the joint; the first member of a joint in the top chord is that which is first met on entering the truss in a counterclockwise direction round the joint.

In the ΣM-tables all the members are included and again the clockwise direction for the bottom chord joints and the counterclockwise direction for the top chord joints are observed.

On the end chord, 1-2, a U-table is constructed, as shown; r_{21} the top letter, refers to the top end of the member, and the bottom letter, r_{12}, to the bottom end. Recalling the method of the deformation contour, these r's are the "contours" of the respective ends of the member.

On each of the two bottom chords, 1-3 and 3-4, a table is constructed, one for U_{13} and S_{13}, the other for U_{34} and S_{34}; these quantities are again obtained from Fig. 48(a). Note that the top r and f refer to the left end of the member, while the bottom r and f refer to the right end. For top chord members, tables identical with these U-tables would be used.

On each of the remaining members, Fig. 48(b), namely, 2-3 and 2-4, place two tables, as shown. It will be seen that the f and the r at the top refer to the top end of the member, while the lower r and f refer to the lower end of the member. The letters on the U_{24}-tables need no explanation; the remaining tables, namely, one on each end of every member, will be explained

later, as they come into use only after the problem of solving for the x and the y have been completed.

The first columns of the ΣM-tables are now filled with the values of the S for the members denoted at the sides. Thus, insert S_{31}, S_{32}, and S_{34} for the ΣM_3-table.

Consider one of the bottom ΣK-tables, say, the ΣK_3-table. Opposite K_{A3} and below the member, 3-2, place the value of K_{A3}, found from Fig. 48(a). In the space directly below, fill in the value of K_{B3} already found, sum the two quantities, and place the result in the adjacent space. This value will now refer to the member, 3-4. If there were more members at the joint, the table would be extended in the following manner: Suppose there were a K_{x3} and a member, 3-n: Directly below the value last found, would be placed the value of K_{x3}; add the two and put the sum in the adjacent space, and so on, for more members.

The ΣK-tables for the upper joints differ in that the rotation round the lower joints is clockwise, while that round the upper joints is counterclockwise; hence, use the negative values of the K's in the top K-tables. Otherwise, they are exactly similar to the bottom K-tables.

Recalling the method of deformation contour, the member to the left of a joint is the reference member. Therefore, the set of ΣK-tables is just a neat method of tabulating the changes of angle between the reference member and the other members of a joint.

The next step is to fill in the spaces shown extending out from the main tables, Fig. 48(b). As is evident from Equations (87) to (90), the r of a member at a joint is connected linearly with the reference, r, of that joint, and the constant term in such an equation is the quantity obtained by dividing the sum of the K's of all the angles between the member in question and the reference member by the U of the member considered. Hence, in the space of the U_{13}-table, put the value, $\frac{K_{A1}}{U_{13}}$, and in the space of the U_{34}-table, the value, $\frac{K_3}{U_{34}}$, that is, $\frac{K_{A3} + K_{B3}}{U_{34}}$. In the spaces of the center row of U-tables, however, put the third values, thus, for the lower space in the U_{23}-table, insert $\frac{K_{A3}}{3\,U_{23}}$, and for the upper space, $\frac{-K_{A2}}{3\,U_{23}}$. All the spaces that have been filled up to this stage are marked by crosses.

To proceed with the solution, let the secondary stresses in the member, 1-2, have the values, x and y, that is, let

$$f_{12} = x \qquad (98)$$

and,

$$f_{21} = y \qquad (99)$$

The spaces of the row opposite f_{12} in the U_{12}-table, are filled in with the numbers, $+1, 0, 0$, while those opposite f_{21} are filled in with the number, $0, +1, 0$. These are the coefficients of the x and y and the constant term in the expres-

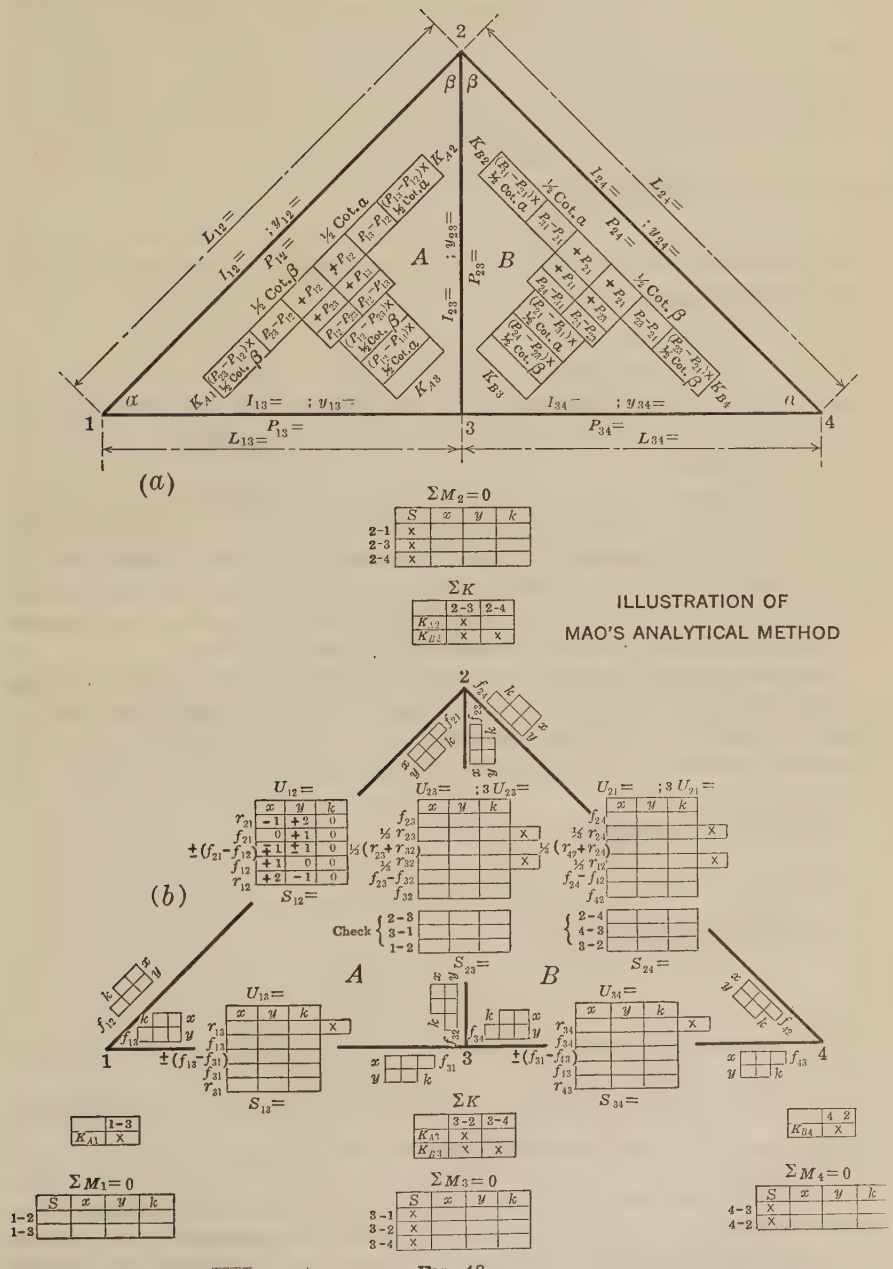

FIG. 48.

sions for the f's in terms of x and y, for, evidently, from Equations (98) and (99),

$$f_{12} = +1 \cdot x + 0 \cdot y + 0$$

and,

$$f_{21} = 0 \cdot x + 1 \cdot y + 0$$

Subtracting f_{12} from f_{21},

$$+ (f_{21} - f_{12}) = -1 \cdot x + 1 \cdot y + 0$$

and by taking the negative value,

$$- (f_{21} - f_{12}) = +x - y + 0$$

Thus are obtained the coefficients, ∓ 1, ± 1, and 0, for the row opposite $\pm (f_{21} - f_{12})$ in the U_{12}-table.

Now, from Equation (82),

$$r_{21} = 2 f_{21} - f_{12} = f_{21} + (f_{21} - f_{12}).$$

Adding the coefficients opposite f_{21} in the U_{12}-table to those belonging to $+ (f_{21} - f_{12})$, gives -1, $+2$, and 0. Similarly, the coefficients opposite r_{12} are $+2$, -1, and 0.

As f_{12} is known, and f_{13} is the only unknown quantity left for Joint (1), the spaces opposite the member, 1-2, in the ΣM_1-table may now be filled. Multiply S_{12} by the coefficients of x, y, and k, opposite f_{12} in the U_{12}-table, that is, $+1$, 0, and 0, and insert the values in the corresponding spaces of the 1-2 row, ΣM_1-table. Now, as $\Sigma M_1 = 0$, the coefficients in the 1-3 row are the negative values of those of the 1-2 row. Hence, the ΣM_1-table is filled.

It is now possible to fill in the coefficients in the f_{12} row of the U_{13}-table, as the coefficients of the x, y, and k, of the 1-3 row, ΣM_1-table, are really a statement that M_{13} is a linear expression in x and y, and, if divided by S_{13}, give the coefficients of x and y and the constant term, to be inserted in the U_{13}-table.

Now, turn to Equation (83), namely,

$$r_{lm} = \frac{U_{ln}}{U_{lm}} \cdot r_{ln} + \frac{K_{mln}}{U_{lm}}$$

For r_{13} and r_{12}, this becomes:

$$r_{13} = \frac{U_{12}}{U_{13}} \cdot r_{12} + \frac{K_{A1}}{U_{13}}$$

The $\frac{K_{A1}}{U_{13}}$ has already been determined, and is the quantity in the extended space of the U_{13}-table. Multiply the coefficient of the x in the r_{12}-expression in the U_{12}-table, by $\frac{U_{12}}{U_{13}}$, and insert the result in the x-space, opposite r_{13} of the U_{13}-table. Repeat this with the y-coefficient, but place the quantity thus obtained from the constant term of r_{12}, above the extended space of the U_{13}-table. On adding this to the quantity in the extended space, the result is the quantity to be inserted in the k-space of r_{13}. It must be noted that, as soon as two rows of any U-table are filled in, the remainder follow, from

Equations (98) and (99). Hence, subtracting the f_{13}-coefficients from the r_{13}-coefficients, gives the $+(f_{13}-f_{31})$-coefficients; the correct signs to take care of the $\pm(f_{13}-f_{31})$-coefficients are placed on the side. Adding these coefficients, with the lower signs, to the coefficients in the row immediately above, gives the coefficients of x, y and the constant term for f_{31}. Finally, adding the set of quantities in the f_{31}-row to that immediately above, gives r_{31}.

Turning now to the U_{23}-table, note that Equation (83) becomes:

$$r_{32} = \frac{U_{31}}{U_{32}} \cdot r_{31} + \frac{K_{A3}}{U_{32}}$$

or,

$$\frac{1}{3} r_{32} = \frac{U_{31}}{3\,U_{32}} \cdot r_{31} + \frac{K_{A3}}{3\,U_{32}}$$

from which to fill in the spaces for $\frac{1}{3} r_{32}$. The constant term of this expression is already in the extended space opposite $\frac{1}{3} r_{32}$. The factor with which to multiply the various quantities in the r_{31}-row of the U_{13}-table is, therefore, $\frac{U_{31}}{3\,U_{32}}$. Note, here again, the k-term resulting from this operation is placed immediately above the extended space of $\frac{1}{3} r_{32}$. From the fact that,

$$\frac{1}{3} r_{23} = \frac{U_{21}}{3\,U_{23}} \cdot r_{21} + \frac{-K_{A2}}{3\,U_{23}}$$

proceed in exactly a similar way to fill the spaces of the $\frac{1}{3} r_{23}$-row of the U_{23}-table. With two rows completed the remaining spaces are readily filled in. Adding the $\frac{1}{3} r_{23}$-row to the $\frac{1}{3} r_{32}$-row fills the spaces that lie between these rows. Adding the $\frac{1}{3} r_{23}$-row to the $\frac{1}{3}(r_{23} + r_{32})$-row gives the f_{23}-row; a reference to Equation (85) proves this. The remainder follows. The U-tables of the three members of the triangle, A, are now complete.

To fill in the check-table on the member, 2-3, turn to Equation (81) and express it in terms of the quantities of the ΔA. Thus,

$$\left.\begin{aligned} K_{A1} &= U_{13}(2f_{13}-f_{31}) - U_{12}(2f_{12}-f_{21}) \\ K_{A2} &= U_{21}(2f_{21}-f_{12}) - U_{23}(2f_{23}-f_{32}) \\ K_{A3} &= U_{32}(2f_{32}-f_{23}) - U_{31}(2f_{31}-f_{13}) \end{aligned}\right\} \quad \ldots\ldots\ldots\ldots (100)$$

However, as the sum of the three angles of a triangle is constant,

$$K_{A1} + K_{A2} + K_{A3} = 0$$

Note that $U_{13} = U_{31}$, $U_{21} = U_{12}$, and $U_{32} = U_{23}$. Adding Equations (100) and dividing by 3,

$$U_{13}(f_{13}-f_{31}) + U_{21}(f_{21}-f_{12}) + U_{32}(f_{32}-f_{23}) = 0$$

that is,

$$-U_{13}(f_{13}-f_{31}) - U_{21}(f_{21}-f_{12}) + U_{32}(f_{23}-f_{32}) = 0.$$

Hence, multiply the $(f_{23} - f_{32})$-coefficients in the U_{23}-table by U_{23}, to obtain the coefficients in the 2-3 row of the check-table. Corresponding quantities are found from the U_{13} and U_{12}-tables, noting that the lower signs of the coefficients are used in each case. If the sum of the x-coefficients in the check-table, of the y-coefficients, and also the sum of the constant terms, is zero, the check is complete. In filling all the remaining tables, it will be found that the relation, $\Sigma M = 0$, is not used at all in completing the ΣM-tables for the last two joints—in this case, the ΣM_2 and ΣM_4-tables.

Adding the three columns in each, an expression is obtained from the M_2-table of the form $(a x + b y + c)$; but as $\Sigma M_2 = 0$,

$$a x + b y + c = 0$$

Similarly, from $\Sigma M_4 = 0$, results an equation such as,

$$a' x + b' y + c' = 0$$

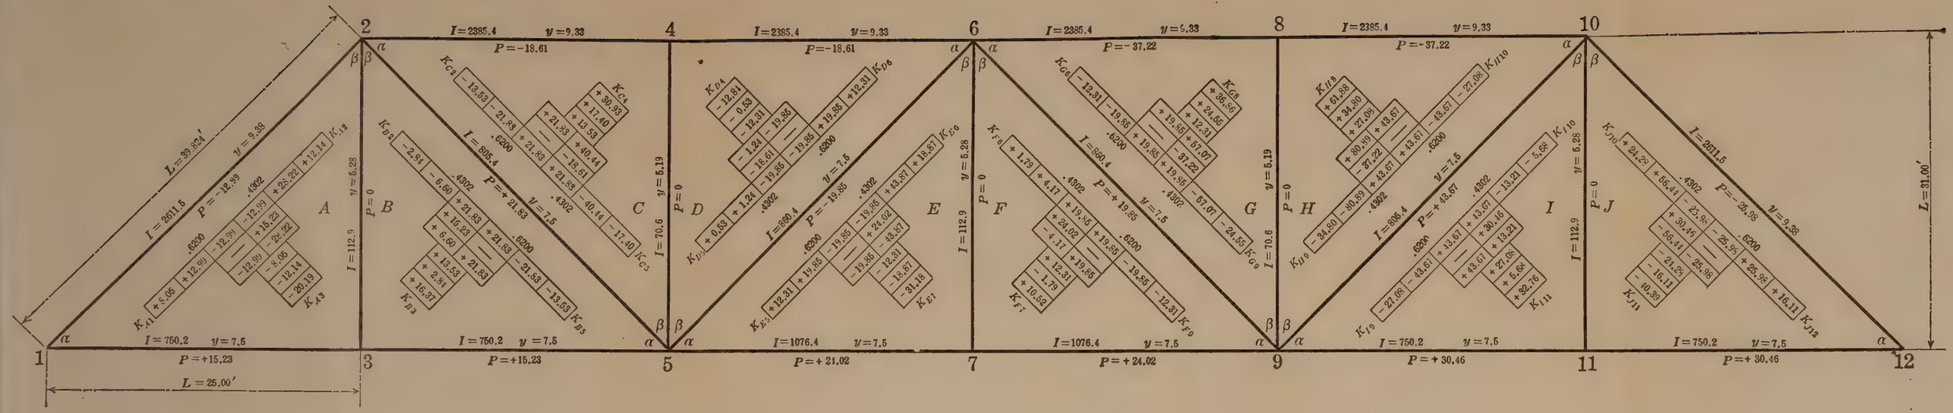
By solving for x and y, from these equations are obtained what were assumed to be known at the outset, namely, f_{12} and f_{21}. Next fill in the small tables around the joints (Fig. 48(b)); these tables have been mentioned, but not explained. Take the table for f_{31}. Transfer the k-value, found in the f_{31}-row of the U_{13}-table, to the space next to k in the f_{31}-table. Multiply the x-coefficient of f_{31} in the U_{13}-table by the value of x just found, and insert the result in the space next to x in the f_{31}-table, and, similarly, for the y-space. Now, add these two quantities, and insert the result in the space above that containing the k-value. Add the k-value to the quantity above it, and place the result in the last space of the f_{31}-table. The quantity thus obtained is the secondary stress of the member, 1-3, for End 3. The computer should proceed in the same manner for all the f-tables and thus determine all the secondary stresses.

PART III.—A CRITICAL COMPARISON BETWEEN THE METHODS OF SOLVING SECONDARY STRESSES IN BRIDGE TRUSSES

1.—Introduction

Many methods of computing the secondary stresses in the trusses of a bridge have been described. At once the question arises: "Which one is the best in its practical application"? In order to arrive at a definite conclusion, it is proposed to apply each method in turn to the same bridge under a load, identical for all the methods. Many comparisons have been made, generally for a bridge loaded symmetrically. This comparison will be for an unsymmetrical load, by which each method will be tested in the severest manner; the one best enduring the test will undoubtedly be the best method in practice.

Plate I and Figs. 49 and 50 show the design of a 150-ft., common standard through riveted Warren truss bridge in present use. The trusses are composed entirely of triangular elements and if they had frictionless hinges would be regarded as statically determinate. Therefore, each of the methods may be applied without adding any further explanations to the theoretical investigations already given.



SOLUTION OF EQUATIONS

From $\Sigma M_{10} = 0$ and $\Sigma M_{12} = 0$,

$$+3\,639\,544\,x - 137\,223\,y = -1\,406\,877$$
$$+3\,579\,438\,x - 718\,960\,y = -3\,106\,013,$$

i. e., $+26.522342\,x - \quad y = -10.2524868$

$+11.933123\,x - \quad y = -4.3201472,$

i. e., $+14.589719\,x \quad = -5.9323396$

$x = -0.40661,$

$y = -4.85214 + 4.32615$

$= -0.53199$

LEGEND

I = Moment of Inertia in in.⁴

y = Extreme Fibre Distance in ins.

L = Length of Member in ft.

$U = L/y$

S = Section Modulus $= I/y$

P = Primary Stress in lbs. per sq. in.

f_{mn} = Secondary Stress In Member mn, at end m, in lbs.per sq. in.

$2K_{Nn}$ = Change of Angle in Triangle N at Vertex n

ΣM_m = Sum of Moments around Joint m. Positive Moments Counter Clockwise

$x = f_{12}$

$y = f_{21}$

Loading: 1500 lbs. at Joint 9.

FORMULAE

$K_{Nm} = (P_{nq} - P_{mn})\cdot\text{Cot. } \beta/2$

$K_{Nq} = (P_{mn} - P_{nq})\ \text{Cot. } \beta/2 + (P_{mn} - P_{mq})\ \text{Cot. } \alpha/2$

$f_{mn} = a_{mn}x + b_{mn}y + k_{mn}$, where a, b and k are Constants

$r_{mn} = 2f_{mn} - f_{mn}$

$= \frac{U_{mp}}{U_{mn}}\, r_{mp} + \frac{\Sigma^{m}_{mp} K_m}{U_{mn}}$, where mp is the Reference Member for Joint m and ΣK is Negative for Top Chord Joints

$r_{nm} = 3f_{mn} - 2r_{mn}$

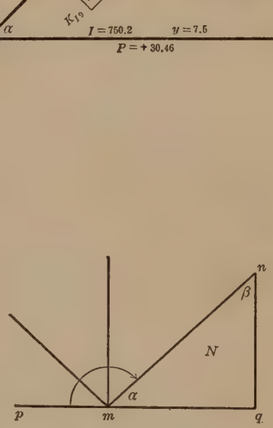
$f_{mn} = \frac{1}{3} r_{mn} + \frac{1}{3}(r_{mn} + r_{nm})$

$f_{mn} - f_{nm} = \frac{1}{3} r_{mn} - \frac{1}{3} r_{nm} = r_{mn} - f_{mn}$

$\Sigma M_m = \Sigma S_{mn} \cdot f_{mn} = 0$

Check for Every Triangle N:

$U_{mq}(f_{qm} - f_{mq}) + U_{nq}(f_{nq} - f_{qn}) + U_{mn}(f_{mn} - f_{nm}) = 0$



$\Sigma M_0 = 0$

Because influence lines are to be used extensively in this study, a single load of definite value is chosen. Influence lines deal with units of load; such a unit may be 1 lb., 1 kip, or 1 000 lb., 1 ton, etc. Here the kip will be adopted as the unit. When the truss has a load of 1 kip at the central panel point of the bottom chord, the left-hand reaction is ½ kip. If the load were 1½ kips placed at the first panel point to the right of the center, the left-hand reaction would again be ½ kip. Finally, if it were 3 kips placed at the panel point to the right, two panel distances from the center, the left-hand reaction would still be ½ kip. It will be found that several members on the left side of the truss are stressed equally under the 1-kip and 1½-kip loads, while an even greater number are stressed equally under the 1½-kip and the 3-kip loads. This method of loading a bridge for the determination of its secondary stresses is due to Professor Turneaure; its advantages will be shown later. In this study, the load will be taken as 1½ kips, placed at the panel point just to the right of the center; this is Panel Point (9).

From Plate I and Figs. 49 and 50 are found the moments of inertia, the centers of gravity of sections, the distances to the extreme fibers, the areas of cross-section and the lengths of the members. None of the calculations is reproduced, only the results are given. It should be remembered that E, the modulus of elasticity, may be regarded as unity throughout the investigation.

The work of calculating the secondary stresses in the trusses when the bridge is under a large number of concentrated loads, will not be appreciably greater than when a single load is considered. The secondary stresses depend on the set of elongations of all the members considering the bridge as statically determinate. The actual work of determining the secondary stresses from the set of elongations under many loads has, therefore, exactly the same weight as for a single load; there is, of course, a little more preliminary work necessary in calculating the elongations.

As was stated previously, the exact method of Manderla (see page 9) is one that involves a great amount of work, and gives results that differ little from those obtained by the modified method. This modified method is generally known as Manderla's method. No solution is made by the exact method; the method, designated "Manderla" in this comparison, is the modified form, due to Winkler. The whole investigation was facilitated by the use of a calculating machine.

2.—Application of Methods

Manderla's Method.—In order to avoid repetition, only one computation was prepared to illustrate the two methods of setting about a solution. The first method would contain the solution of a set of simultaneous linear equations by means of the method of substitution, while the second would solve a set of simultaneous linear equations by means of Gauss' theory of normal equations. Otherwise, the first method would be similar to the second. Only the results of the first method are given in Table 24.

Manderla-Gauss Method.—The formation of the equations for the truss and loading shown in Fig. 51 and Plate I, is given in Table 1. The re-

Table 2 is obtained from the dimensions of the truss and is self-explanatory. Use is then made of Equations (2), namely,

$$E \cdot \Delta \alpha = (s_1 - s_2) \cot \gamma + (s_1 - s_3) \cot \beta$$
$$E \cdot \Delta \beta = (s_2 - s_3) \cot \alpha + (s_2 - s_1) \cot \gamma$$
$$E \cdot \Delta \gamma = (s_3 - s_1) \cot \beta + (s_3 - s_2) \cot \alpha$$

to obtain Table 3.

The method of constructing Tables 3 and 4 and hence of forming the expression for the equality of the moments acting at each joint to zero are given in standard works on structural design.*

A little practice will enable the engineer to perform the latter operation mechanically.

TABLE 3.—MANDERLA-GAUSS METHOD. ANGLES AND FUNCTIONS.

Table 5 is then constructed. It represents the solution of the twelve equations already formed; Gauss' method of normal equations is used. Textbooks on least squares explain the theory; the remarks in the second column ought, however, to be sufficient to indicate the reasoning. The check term in the last column is the sum of all the coefficients of the τ's in an equation, together with its absolute term. Thus, + 15.930 + 5.464 + 2.501 + 2.796 = + 26.691 for Equation (1). All the absolute terms are divided by 10, in order to obtain the three decimal places of the τ-coefficients. The resulting τ's are, therefore, to be multiplied by 10, before being used in Table 5.

* See Johnson, Bryan, and Turneaure, "Theory of Framed Structures."

	.....	7.965	.....	.....	.....	+176.05

When the operations on Equations (1) and (2), Table 5, have been performed, Equation I is obtained by adding the two equations above. The check terms also are added. The final check for Equation I is that the sum of the coefficients of its τ's, together with its absolute term, must give the check term already found by adding -9.155 and $+45.951$, namely, $+36.796$. This check is applied for Equations II, III, IV, etc., until finally Equation XI is reached, which gives the value for τ_{12}. Going back to Equations X, IX, VIII, etc., τ_{10}, τ_{11}, τ_8, etc., are solved in turn.

These values are now inserted in Table 6, and by use of Equation (27), the τ's of all the members are obtained. For example, $\tau_{12} = -2.16$. In order to get the τ of the next member, namely, 1-3, it is necessary to add the δ-angle of

TABLE 6.—(*Continued*).

9	$\tau_{9.7}$	$= +79.28 - 24.61$	$M_{9.7} = 3.588\ (+158.56 - 35.70) \times 2 = +881.64$ in.-lb.
	$\tau_{9.6}$	$= +54.67 - 46.03$	$M_{9.6} = 1.800\ (+109.34 - 55.94) \times 2 = +192.24$ in.-lb.
	$\tau_{9.8}$	$= +8.64 - 65.24$	$M_{9.8} = 0.190\ (+17.28 + 28.76) \times 2 = +17.50$ in.-lb.
	$\tau_{9.10}$	$= -56.60 - 54.15$	$M_{9.10} = 1.685\ (-113.20 + 66.35) \times 2 = -157.88$ in.-lb.
	$\tau_{9.11}$	$= -110.75$	$M_{9.11} = 2.501\ (-221.50 + 34.88) \times 2 = -933.47$ in.-lb.
10	$\tau_{10.12}$	$= +31.48 + 45.52$	$M_{10.12} = 5.464\ (+62.96 - 4.12) \times 2 = +643.00$ in.-lb.
	$\tau_{10.11}$	$= +77.00 - 10.65$	$M_{10.11} = 0.303\ (+154.00 + 99.68) \times 2 = +153.73$ in.-lb.
	$\tau_{10.9}$	$= +66.35 - 54.15$	$M_{10.9} = 1.685\ (+132.70 - 56.60) \times 2 = +256.46$ in.-lb.
	$\tau_{10.8}$	$= +12.20$	$M_{10.8} = 7.951\ (+24.40 - 90.63) \times 2 = -1\,053.19$ in.-lb.
11	$\tau_{11.9}$	$= +34.88 + 64.80$	$M_{11.9} = 2.501\ (+69.76 - 110.75) \times 2 = -205.03$ in.-lb.
	$\tau_{11.10}$	$= +99.68 - 77.74$	$M_{11.10} = 0.303\ (+199.36 + 77.00) \times 2 = +167.47$ in.-lb.
	$\tau_{11.12}$	$= +21.94$	$M_{11.12} = 2.501\ (+43.88 - 36.34) \times 2 = +37.72$ in.-lb.
12	$\tau_{12.11}$	$= -36.34 + 32.22$	$M_{12.11} = 2.501\ (-72.68 + 21.94) \times 2 = -253.80$ in.-lb.
	$\tau_{12.10}$	$= -4.12$	$M_{12.10} = 5.464\ (-8.24 + 31.48) \times 2 = +253.97$ in.-lb.

the angle between the members; this is found from Table 4 to be + 16.11. The bending moments are then obtained by making use of Equations (39). A check is applied at this juncture; the sum of the bending moments around a joint must be zero.

Table 7 then follows directly. It is to be noted that when a member like 1-3 is subjected to the bending moment, + 113.35 in-lb., positive in a counter-clockwise direction, the top set of fibers of Member 1-3, at End (1) is in tension and the bottom set is in compression. In other words, the quantities, — 0.41, + 0.41, ± 1.13, in the last column of Table 7, Joint (1), are the secondary stresses of the top set of Member 1-2, the bottom set of Member 1-2, the top set of Member 1-3, and the bottom set of Member 1-3, in the order named, which is also the order due to a clockwise movement around Joint (1). The quantities, — 0.41 and + 0.41, are separated because the distance of the top set of fibers from the neutral plane, through the center of gravity, differs from that of the bottom set.

Müller-Breslau's Method.—The work of solving the problem is given in Tables 8 to 10, inclusive, and Fig. 52. For this solution the K's and the changes of angle were just taken from Table 4. The ρ's, which are the $\frac{Ml}{I}$-quantities, are written at both ends of all the members. Thus, ρ_1 to ρ_{42}, inclusive, are obtained. Six times the changes of angle are the quantities found in the corners.

TABLE 7.—MANDERLA-GAUSS METHOD. SECONDARY STRESSES AND MEMBERS.

Joint.	Member.	Extreme fiber distance, C, in inches.	I, in inches^4.	$\frac{C}{I}$	M, in pounds.	$f = \frac{C}{I} \times M$, in pounds per square inch.

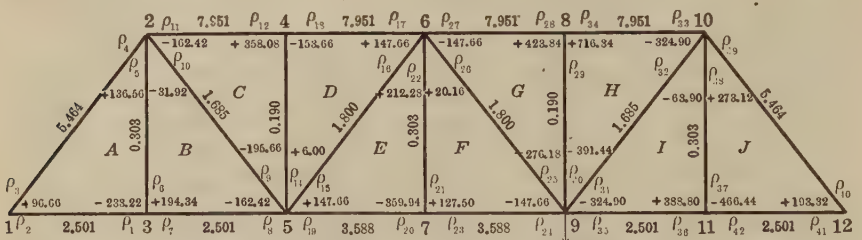
It is assumed that the two quantities, ρ_1 and ρ_2, on Ends (3) and (1) of the member, 1-3, respectively, are known. $\Sigma M = 0$ for Joint (1), that is, $K_{12} \cdot \rho_3 + K_{13} \cdot \rho_2 = 0$, expressing ρ_3 in terms of ρ_2. Three of the six quantities, ρ_1, ρ_2, ρ_3, ρ_4, ρ_5, and ρ_6, therefore, are known. Applying Equations (47), (48), and (49), ρ_4, ρ_5, and ρ_6 are given in terms of ρ_1 and ρ_2 as shown.

$\Sigma M = 0$ for Joint (3) gives an expression for ρ_7 in terms of ρ_1 and ρ_2. This process is continued until the $\Sigma M = 0$ equations for Joints (10) and (12) give the solution of ρ_1 and ρ_2. On substituting these values, ρ_3, ρ_4, ρ_5, * * * ρ_{42}, are obtained as shown in Table 9. Table 10 is self-explanatory. Note that a clockwise moment was assumed to be positive at the start (see

page 19). This means that the top fiber of the member, 1-3, End (1), is + 1.14, the result of the ρ_2 being — 45.60. This agrees with the signs of the fiber stresses found in Table 7.



SECONDARY STRESSES BY MULLER-BRESLAU'S METHOD

REMARKS.

The numbers written on the members are the $K = {}^{I}/_{l}$ - Values;
e. g. 5.464 on 1 - 2 = K_{12}

The numbers written in the corners are the Changes of Angle, multiplied by 6E:
e. g. +96.66 in corner of Triangle $A = 6E.\ \delta A1.$

FIG. 52.

Ritter's Method.—In Fig. 53 and Tables 11 and 12 are given the results of applying Ritter's graphical method to a solution of the truss. The unit stresses are again assumed to be known, and with these the changes of angle (see page 9) are determined graphically as indicated in Fig. 53 and Table 11.

The quantities, $\frac{I}{l}$, are the forces of the force and equilibrium polygons. As already described (page 24), these forces are laid out, spaced by horizontal distances equal to the $E \cdot \Delta\theta$'s of Table 11. This gives 3, 5, 1, 4, in order from left to right for Joint (2). The scale used is of importance. Thus (Fig. 53 (2)), 5 is at a distance corresponding to 2.72 to the left of 4, representing the change of angle, $C\,2 = -27.2$, in Table 11. When all these forces have been laid out, draw the force polygons at the sides, with the forces in the order met in going from left to right along the horizontal. Thus, the force polygon of Joint (2) has the forces, 3, 5, 1, 4, in the order named, Force 3 meaning $\frac{I_{23}}{l_{23}}$, etc. The scale of the force polygons is arbitrary.

Draw the equilibrium polygons for the undisplaced forces, obtaining the positions of their resultants. By means of Equations (53), are found the distances to which all these forces have to be displaced, and then the resultant of these forces by means of a second set of equilibrium polygons. The resultants just found will be displaced from the previous resultants. Again, use Equations (53) to obtain a fresh set of resultants, and so on, until it is found that every resultant after a certain number of trials coincides with the corresponding resultant of the preceding trial. The diagrams of Fig. 53 represent the result of the sixth trial, when the variation between every resultant of displaced forces and the corresponding resultant belonging to the fifth trial was found to be negligible.

TABLE 8.—Müller-Breslau Method. Equations Involving ρ_1 to ρ_{42}

$\Sigma M = 0$ gives :

$$
\left.\begin{aligned}
&5.464\,\rho_3 + 2.501\,\rho_2 = 0 \quad (1)\\
&7.951\,\rho_{11} + 1.685\,\rho_{10} + 0.303\,\rho_5 + 5.464\,\rho_4 = 0 \quad (2)\\
&2.501\,\rho_1 + 0.303\,\rho_6 + 2.501\,\rho_7 = 0 \quad (3)\\
&7.951\,\rho_{18} + 0.190\,\rho_{18} + 7.951\,\rho_{12} = 0 \quad (4)\\
&2.501\,\rho_8 + 1.685\,\rho_9 + 0.190\,\rho_{14} + 1.800\,\rho_{15} + 3.588\,\rho_{19} = 0 \quad (5)\\
&7.951\,\rho_{27} + 1.800\,\rho_{26} + 0.303\,\rho_{22} + 1.800\,\rho_{16} + 7.951\,\rho_{17} = 0 \quad (6)\\
&3.588\,\rho_{20} + 0.303\,\rho_{21} + 3.588\,\rho_{23} = 0 \quad (7)\\

&3.588\,\rho_{24} + 1.800\,\rho_{25} + 0.190\,\rho_{30} + 1.685\,\rho_{31} + 2.501\,\rho_{35} = 0 \quad (9)\\
&5.464\,\rho_{39} + 0.303\,\rho_{38} + 1.685\,\rho_{32} + 7.951\,\rho_{33} = 0 \quad (10)\\
&2.501\,\rho_{36} + 0.303\,\rho_{37} + 2.501\,\rho_{42} = 0 \quad (11)\\
&2.501\,\rho_{41} + 5.464\,\rho_{40} = 0 \quad (12)
\end{aligned}\right\} \text{.....}
$$

Joint (1) : $5.464\,\rho_3 + 2.501\,\rho_2 = 0$

or, $\rho_3 = -0.4577\,\rho_2$.

Triangle A :

$$
\left\{\begin{aligned}
(2\,\rho_3 - \rho_4) &= +96.66 + 2\,\rho_2 - \rho_1\\
\rho_4 &= -96.66 - 2\,\rho_2 + \rho_1 + 2\,\rho_3\\
&= -96.66 + \rho_1 - 2.9154\,\rho_2\\
(\rho_5 - \rho_4) &= +136.56 + (\rho_1 - \rho_2)\\
\rho_5 &= +136.56 + \rho_1 - \rho_2 + \rho_4\\
&= +39.90 + 2\,\rho_1 - 3.9154\,\rho_2\\
(\rho_1 - \rho_6) &= -233.22 + \rho_3 - \rho_4\\
\rho_6 &= +233.22 - \rho_3 + \rho_4 + \rho_1\\
&= +136.56 + 2\,\rho_1 - 2.4577\,\rho_2
\end{aligned}\right.
$$

Joint (3) : $2.501\,\rho_1 + 0.303\,\rho_6 + 2.501\,\rho_7 = 0$

$$\therefore \rho_7 = -\rho_1 - 0.1212\,\rho_6$$
$$= -16.55 - 1.2424\,\rho_1 + 0.2979\,\rho_2$$

Triangle B :

$$
\left\{\begin{aligned}
2\,\rho_6 - \rho_5 &= +194.34 + 2\,\rho_7 - \rho_8\\
\rho_8 &= +194.34 + 2\,\rho_7 - 2\,\rho_6 + \rho_5\\
&= -71.98 - 4.4848\,\rho_1 + 1.5958\,\rho_2\\
\rho_8 - \rho_9 &= -162.42 + \rho_6 - \rho_5\\
\rho_9 &= +162.42 - \rho_6 + \rho_5 + \rho_8\\
&= -6.22 - 4.4848\,\rho_1 + 0.1381\,\rho_2\\
\rho_{10} - \rho_5 &= -31.92 + \rho_8 - \rho_7\\
\rho_{10} &= -31.92 + \rho_8 - \rho_7 + \rho_5\\
&= -47.45 - 1.2424\,\rho_1 - 2.6175\,\rho_2
\end{aligned}\right.
$$

Joint (2) : $7.951\,\rho_{11} + 1.685\,\rho_{10} + 0.303\,\rho_5 + 5.464\,\rho_4 = 0$

$$\therefore \rho_{11} = -0.2119\,\rho_{10} - 0.0381\,\rho_5 - 0.6872\,\rho_4$$
$$= +74.93 - 0.5001\,\rho_1 + 2.7073\,\rho_2$$

Triangle C :

$$
\left\{\begin{aligned}
2\,\rho_{11} - \rho_{12} &= -162.42 + 2\,\rho_{10} - \rho_9\\
\rho_{12} &= +162.42 - 2\,\rho_{10} + \rho_9 + 2\,\rho_{11}\\
&= +400.96 - 3.0002\,\rho_1 + 10.7877\,\rho_2\\
\rho_{18} - \rho_{12} &= +358.08 + \rho_9 - \rho_{10}\\
\rho_{18} &= +358.08 + \rho_9 - \rho_{10} + \rho_{12}\\
&= +800.27 - 6.2426\,\rho_1 + 13.5433\,\rho_2\\
\rho_9 - \rho_{14} &= -195.66 + \rho_{11} - \rho_{12}\\
\rho_{14} &= +195.66 - \rho_{11} - \rho_{12} + \rho_9\\
&= +515.47 - 6.9849\,\rho_1 + 8.2185\,\rho_2
\end{aligned}\right.
$$

Joint (4) : $7.951\,\rho_{18} + 0.190\,\rho_{18} + 7.951\,\rho_{12} = 0$

$$\therefore \rho_{18} = -0.0239\,\rho_{18} - \rho_{12}$$
$$= -420.09 + 3.1494\,\rho_1 - 10.9841\,\rho_2$$

Triangle D :

$$
\left\{\begin{aligned}
2\,\rho_{18} - \rho_{17} &= -153.66 + 2\,\rho_{18} - \rho_{14}\\
\rho_{17} &= +153.66 - 2\,\rho_{18} - \rho_{14} + 2\,\rho_{18}\\
&= -1\,771.59 + 11.7991\,\rho_1 - 40.8363\,\rho_2\\
\rho_{16} - \rho_{17} &= +147.66 + \rho_{14} - \rho_{13}\\
\rho_{16} &= +147.66 + \rho_{14} - \rho_{13} + \rho_{17}\\
&= -1\,908.73 + 11.0568\,\rho_1 - 46.1611\,\rho_2\\
\rho_{14} - \rho_{15} &= +6.00 + \rho_{18} - \rho_{17}\\
\rho_{15} &= -6.00 - \rho_{18} + \rho_{17} + \rho_{14}\\
&= -842.08 + 1.6488\,\rho_1 - 21.6337\,\rho_2
\end{aligned}\right.
$$

Joint (5) : $2.501\,\rho_8 + 1.685\,\rho_9 + 0.190\,\rho_{14} + 1.800\,\rho_{15} + 3.588\,\rho_{19} = 0$

$$\therefore \rho_{19} = -0.6970\,\rho_8 - 0.4696\,\rho_9 - 0.0530\,\rho_{14} - 0.5017\,\rho_{15}$$
$$= +448.22 + 4.7670\,\rho_1 + 9.2408\,\rho_2$$

Triangle E :

$$
\left\{\begin{aligned}
2\,\rho_{15} - \rho_{16} &= +117.66 + 2\,\rho_{19} - \rho_{20}\\
\rho_{20} &= +147.66 + 2\,\rho_{19} + \rho_{16} - 2\,\rho_{15}\\
&= +819.43 + 17.2612\,\rho_1 + 15.5879\,\rho_2\\
\rho_{20} - \rho_{21} &= -359.94 + \rho_{15} - \rho_{16}\\
\rho_{21} &= +359.94 - \rho_{15} + \rho_{16} + \rho_{20}\\
&= +112.67 + 26.6532\,\rho_1 - 8.9395\,\rho_2\\
\rho_{22} - \rho_{16} &= +212.28 + \rho_{20} - \rho_{19}\\
\rho_{22} &= +212.28 + \rho_{20} - \rho_{19} + \rho_{16}\\
&= -1\,325.24 + 23.5510\,\rho_1 - 39.8140\,\rho_2
\end{aligned}\right.
$$

TABLE 8.—(*Continued*).

Joint (7):

$$3.588\,\rho_{20} + 0.303\,\rho_{21} + 3.588\,\rho_{23} = 0$$
$$\rho_{23} = -\rho_{20} - 0.0844\,\rho_{21}$$
$$= -828.94 - 19.5107\,\rho_1 - 14.8334\,\rho_2$$

Triangle F:

$$\left\{\begin{array}{lll} 2\,\rho_{21} - \rho_{22} &=& +127.50 + 2\,\rho_{23} - \rho_{24} \\ \rho_{24} &=& +127.50 + 2\,\rho_{23} + \rho_{22} - 2\,\rho_{21} \\ &=& -3\,080.96 - 68.7768\,\rho_1 - 51.6018\,\rho_2 \\ \rho_{24} - \rho_{25} &=& -147.66 + \rho_{21} - \rho_{22} \\ \rho_{25} &=& +147.66 - \rho_{21} + \rho_{22} + \rho_{24} \\ &=& -4\,371.21 - 71.8790\,\rho_1 - 82.4763\,\rho_2 \\ \rho_{26} - \rho_{22} &=& +20.16 + \rho_{24} - \rho_{23} \\ \rho_{26} &=& +20.16 + \rho_{24} - \rho_{23} + \rho_{22} \\ &=& -3\,557.10 - 25.7151\,\rho_1 - 76.5824\,\rho_2 \end{array}\right.$$

Joint (6):

$$7.951\,\rho_{27} + 1.800\,\rho_{26} + 0.303\,\rho_{22} + 1.800\,\rho_{16} + 7.951\,\rho_{17} = 0$$
$$\rho_{27} = -0.2264\,\rho_{26} - 0.0381\,\rho_{22} - 0.2264\,\rho_{16} - \rho_{17}$$
$$= +3\,059.55 - 9.3778\,\rho_1 + 70.1424\,\rho_2$$

Triangle G:

$$\left\{\begin{array}{lll} 2\,\rho_{27} - \rho_{28} &=& -147.66 + 2\,\rho_{26} - \rho_{25} \\ \rho_{28} &=& +147.66 - 2\,\rho_{26} + \rho_{25} + 2\,\rho_{27} \\ &=& +9\,009.75 - 39.2044\,\rho_1 + 210.9733\,\rho_2 \\ \rho_{29} - \rho_{28} &=& +423.84 + \rho_{25} - \rho_{26} \\ \rho_{29} &=& +423.84 + \rho_{28} + \rho_{25} - \rho_{26} \\ &=& +8\,619.48 - 85.3683\,\rho_1 + 205.0794\,\rho_2 \\ \rho_{25} - \rho_{30} &=& -276.18 + \rho_{27} - \rho_{28} \\ \rho_{30} &=& +276.18 - \rho_{27} + \rho_{28} + \rho_{25} \\ &=& +1\,855.17 - 101.7056\,\rho_1 + 58.3546\,\rho_2 \end{array}\right.$$

Joint (8):

$$7.951\,\rho_{34} + 0.190\,\rho_{29} + 7.951\,\rho_{28} = 0$$
$$\rho_{34} = -0.0239\,\rho_{29} - \rho_{28}$$
$$= -9\,215.76 + 41.2447\,\rho_1 - 215.8747\,\rho_2$$

Triangle H:

$$\left\{\begin{array}{lll} 2\,\rho_{34} - \rho_{36} &=& +716.34 + 2\,\rho_{29} - \rho_{30} \\ \rho_{33} &=& -716.34 - 2\,\rho_{29} + \rho_{30} + 2\,\rho_{34} \\ &=& -34\,531.65 + 151.5204\,\rho_1 - 783.5536\,\rho_2 \\ \rho_{32} - \rho_{33} &=& -324.90 + \rho_{30} - \rho_{29} \\ \rho_{32} &=& -324.90 + \rho_{33} + \rho_{30} - \rho_{29} \\ &=& -41\,620.86 + 136.1831\,\rho_1 - 930.2784\,\rho_2 \\ \rho_{30} - \rho_{31} &=& -391.44 + \rho_{34} - \rho_{33} \\ \rho_{31} &=& +391.44 - \rho_{34} + \rho_{33} + \rho_{30} \\ &=& -23\,069.28 + 8.5701\,\rho_1 - 509.3243\,\rho_2 \end{array}\right.$$

Joint (9):

$$3.588\,\rho_{24} + 1.800\,\rho_{25} + 0.190\,\rho_{30} + 1.685\,\rho_{31} + 2.501\,\rho_{35} = 0$$
$$\rho_{35} = -1.4346\,\rho_{24} - 0.7197\,\rho_{25} - 0.0760\,\rho_{30} - 0.6737\,\rho_{31}$$
$$= +22\,966.69 + 152.3544\,\rho_1 + 472.0830\,\rho_2$$

Triangle I:

$$\left\{\begin{array}{lll} 2\,\rho_{31} - \rho_{32} &=& -324.90 + 2\,\rho_{35} - \rho_{36} \\ \rho_{36} &=& -324.90 + 2\,\rho_{35} + \rho_{32} - \rho_{31} \\ &=& +50\,126.18 + 423.7517\,\rho_1 + 1\,032.5362\,\rho_2 \\ \rho_{33} - \rho_{32} &=& -63.90 + \rho_{36} - \rho_{35} \\ \rho_{33} &=& -63.90 + \rho_{36} - \rho_{35} + \rho_{32} \\ &=& -14\,525.27 + 407.5804\,\rho_1 - 369.8252\,\rho_2 \\ \rho_{36} - \rho_{37} &=& +388.80 + \rho_{31} - \rho_{32} \\ \rho_{37} &=& -388.80 - \rho_{31} + \rho_{32} + \rho_{36} \\ &=& +31\,185.80 + 551.3647\,\rho_1 + 611.5821\,\rho_2 \end{array}\right.$$

Joint (11):

$$2.501\,\rho_{36} + 0.303\,\rho_{37} + 2.501\,\rho_{42} = 0$$
$$\rho_{42} = -\rho_{36} - 0.1212\,\rho_{37}$$
$$= -53\,905.90 - 490.5771\,\rho_1 - 1\,106.6600\,\rho_2$$

Triangle J:

$$\left\{\begin{array}{lll} 2\,\rho_{37} - \rho_{38} &=& -466.44 + 2\,\rho_{42} - \rho_{41} \\ \rho_{41} &=& -466.44 + 2\,\rho_{42} + \rho_{38} - 2\,\rho_{37} \\ &=& -185\,175.11 - 1\,676.3032\,\rho_1 - 3\,806.3094\,\rho_2 \\ \rho_{39} + \rho_{38} &=& +273.12 + \rho_{41} + \rho_{42} \\ \rho_{39} &=& +273.12 + \rho_{41} + \rho_{42} + \rho_{38} \\ &=& -145\,521.36 - 777.7228\,\rho_1 - 3\,069.4746\,\rho_2 \\ \rho_{41} - \rho_{40} &=& +193.32 + \rho_{37} + \rho_{38} \\ \rho_{40} &=& -193.32 - \rho_{37} + \rho_{38} + \rho_{41} \\ &=& -231\,079.50 - 1\,820.0875\,\rho_1 - 4\,787.7167\,\rho_2 \end{array}\right.$$

Joints (10) and (12) give the two simultaneous equations:

$$5.464\,\rho_{39} + 0.303\,\rho_{38} + 1\,685\,\rho_{32} + 7.951\,\rho_{33} = 0$$
$$2.501\,\rho_{41} + 5.464\,\rho_{40} = 0$$

In terms of ρ_1 and ρ_2, these become:

$$-1\,144\,222.17 - 2\,691.7733\,\rho_1 - 24\,681.2200\,\rho_2 = 0,$$
$$-1\,725\,741.34 - 14\,137.3924\,\rho_1 - 35\,679.6638\,\rho_2 = 0.$$

that is,

$$+425.081 + \rho_1 + 9.16913\,\rho_2 = 0$$
$$+122.069 + \rho_1 + 2.52378\,\rho_2 = 0.$$
$$\therefore +303.012 + 6.64535\,\rho_2 = 0$$
$$\therefore \rho_2 = -45.5976$$
$$\rho_1 = -6.9907$$

Substituting these values in the ρ-expressions, Table 9 is obtained.

TABLE 9.—MÜLLER-BRESLAU METHOD. SOLUTION OF VALUES OF ρ_3 TO ρ_{42}.

$\rho_3 = +20.8700$
$\rho_4 = -96.66 - 6.9907 + 132.9352 = +29.2845$
$\rho_5 = +39.90 - 13.9814 + 178.5328 = +204.4514$
$\rho_6 = +136.56 - 13.9814 + 112.0652 = +234.6438$
$\rho_7 = -16.55 + 8.6852 - 13.5835 = -21.4483$
$\rho_8 = -71.98 + 31.3519 - 72.7647 = -113.3928$
$\rho_9 = -6.22 + 31.3519 - 6.2970 = +18.8340$
$\rho_{10} = -47.45 + 8.6852 + 119.3517 = +80.5869$
$\rho_{11} = +74.93 + 3.4960 - 123.4464 = -45.0204$
$\rho_{12} = +400.96 + 20.9735 - 491.8932 = -69.9597$
$\rho_{13} = +800.27 + 43.6401 - 617.5420 = +226.3681$
$\rho_{14} = +515.47 + 48.8293 - 374.7439 = +189.5554$
$\rho_{15} = -842.03 - 11.6381 + 986.4448 = +132.7767$
$\rho_{16} = -1\ 908.73 - 77.2948 + 2\ 104.8354 = +118.8106$
$\rho_{17} = -1\ 771.59 - 82.4840 + 1\ 862.0373 = +7.9633$
$\rho_{18} = -420.09 - 22.0165 + 500.8486 = +58.7421$
$\rho_{19} = +448.22 - 33.3247 - 421.3583 = -6.4630$
$\rho_{20} = +819.43 - 120.6679 - 710.7708 = -12.0087$

	$2\mu_{10} = -15.5$	9.49	477.9	0.03972	+0.92
12		9.38		0.03926	−0.91
	$2\mu_{11} = +34.0$	7.5	300	0.05	∓2.55

The quantities, 2 μ, were then listed in Table 12. For example, in the figure for Joint (1), 2′ lies at a distance of 0.7 to the left of R_1, the resultant of the displaced forces. Hence, 2 $\mu_2 = +7.0$ and this is tabulated. Equation (54) is then used to determine the secondary stresses. The moments were to be positive when acting in a clockwise direction. The signs of the secondary stresses, therefore, are justified.

Mohr's Semi-Graphical Method.—The result of applying Mohr's semi-graphical method to the solution of the problem is shown in Fig. 54 and Tables 13 to 16, inclusive. Table 13 is partly filled (the first four columns), when the Williot diagram is drawn. The Δl's are laid out to a convenient scale; this is on the supposition that E is unity. From the completed diagram are then obtained the ρ's to be entered in Column (5) of Table 13, which table can then be completed.

Table 14 is then constructed, by the use of which the equations for the joints may be built (see Equation (59)). Table 15 is the solution of these equations by Gauss' method of normal equations.

Table 16 is then completed, making use of Equation (60). Note, again, that a clockwise bending moment is reckoned to be positive in this analysis. Hence, it is that the + 0.105 of Member 1-2 gives a compressive stress for the top fiber and a tensile stress for the lower fiber of Member 1-2, End (1).

Mohr's Elastic Weight Method.—The solution of the problem by means of Mohr's elastic weight method is given in Fig. 55 and Tables 17 to 22, inclusive. Table 17 is filled out first. Then, the truss is separated into triangles (Fig. 55), and on each is indicated by arrows the direction of following around the chain. Thus, it is a clockwise rotation for ΔA followed by a counter-clockwise rotation for ΔB, etc. At the vertices of each triangle, place the ψ's belonging to that triangle. Thus, in going around Joint (2) of ΔA, the direction is from Member 1-2 to Member 2-3; ψ_2 is, therefore,

$$\lambda_{23} - \lambda_{12} = 0 - (-12.99) = +12.99.$$

Then, place the elastic weights at the third points of the members. Thus, $\phi_{12} = +0.091\, M_{12}$ at the first "third" point on the way from Joint (1) to Joint (2), and $\phi_{21} = -0.091 M_{21}$ at the second, etc.

Assume that M_{12} and M_{21} are known. The $\Sigma M = 0$ for Joint (1) gives Equation I-1 of Table 18. Taking moments of the ϕ's about the u_1-axis in ΔA and also moments of the ψ's about the v_1-axis, marked in ΔA, as the u_1-axis coincides with the v_1-axis on a clockwise rotation of 90°, the sum of the ϕ-moments, together with the sum of the ψ-moments, must be zero. (Refer to Equations (72)). In taking these axes, only one fresh unknown has been introduced, namely, M_{31}; Equation II-1 of Table 18 is the result. By taking moments about the axes, u_2 and v_2, it will be found that Equation II-2 contains only one fresh unknown, namely, M_{23}. Equation II-3 is the result of taking moments about u_3 and v_3.

Then Equation I-3 is the equation representing the fact that $\Sigma M_3 = 0$. The remainder of the equations in Table 18 follow in the same manner. The axes are marked 1, 2, 3, in the order and place, to make sure that only one new unknown is added with every additional moment equation. The height

E = Modulus of elasticity, taken as unity.
A = Area of cross-section of member, in square inches.
S = Total load in member, in pounds.
l = Length of member, in inches.
I = Moment of inertia of member, in inch units.
$\lambda = \frac{S}{EA}$, strain (*Dehnung*).
$\beta = \frac{l}{2\,EI}$, elastic weight (*Masse der Biegsamkeit*).

of the triangles is 31 ft., while the base is 25 ft.; hence, it is that the factors, $\frac{25}{31}$ and $\frac{31}{25}$, appear in the ψ-terms of Table 18.

Table 19 is only a re-arrangement of the equations of Table 18. Table 20 is the result of expressing every M in terms of M_{12} and M_{21}, which is possible by starting at the beginning of Table 19.

It will be found that $\Sigma M_{10} = \Sigma M_{12} = 0$ are two equations that have not been used at all. After solving these, for they are simultaneous linear equations in M_{12} and M_{21}, Table 21 and, finally, Table 22 follow.

It must be noted that positive moments are counterclockwise, hence, the signs are as shown in front of the various secondary stresses.

The results in Table 19 and the following tables have been computed each time to five places of decimals. The writer believed that a good basis for accuracy in all the methods would be to carry out Mohr's elastic weight method to ten places of decimals, the computing machine making this quite possible. It goes without saying that no engineer demands such accuracy; the only justification in the present case is that the method which gave results closest to what may be termed the standard in this investigation was the best for purposes of accuracy combined with speed in obtaining the secondary stresses.

Mao's Graphical Method of Deformation Contour.—Figs. 56 and 57 and Table 23 represent Mao's graphical method applied to the problem. On the truss diagram, Fig. 56 (*a*), the moments of inertia, I, and the unit stresses, P,

are given, also, the U-lines, which are drawn from one end of a member tangent to the circle the center of which is at the other end, and the radius of which is equal to the extreme fiber distance for the member. For example, there is such a line from Joint (1) to the circle of radius, $y = 9.38$ in. at Joint (2). Finally, by Ritter's method the half values of the changes of angle are graphically determined on this diagram. It has been shown (see page 42) that the scales call for the half values of the changes of angle when the lengths of the members are expressed in feet and the fiber distances in inches.

Equations I (11) and I (12) give:

$$0 = -5\,960.53460M_{12} + 222.44247M_{21} - 641\,213.99366$$
$$0 = -7\,272.90718M_{12} - 1\,144.91422M_{21} - 1\,003\,701.14076,$$

that is:

$$0 = -26.795848M_{12} + M_{21} - 2\,882.605977$$
$$0 = -6.352360M_{12} - M_{21} - 876.660560,$$

that is:

$$M_{12} = -113.407836,$$
$$M_{21} = -156.253159.$$

In Fig. 56(b) is shown the force diagram of the section moduli, these being the forces the distances of which from the joints will be the secondary stresses. These S-forces are drawn in directions perpendicular to their various members. The broken lines represent the directions that the R-forces take at the various joints, in order to preserve equilibrium with the S-forces.

The property and deformation lines are then constructed (Fig. 57). All the sets of property lines but one are omitted because any more lines than those given would make the diagram rather confusing. The lines marked K_{A1}, K_{A2}, etc., are the deformation lines in position (see page 45). Then, all the base and vertex lines of all the triangles are located, the full lines being the base lines and the broken lines the vertex lines (see page 51).

Following the instructions to determine the reference contour, $r_{11\cdot9}$ by means of the base and vertex lines of ΔJ, Vertex (11), *via* Vertex (12), and the base and vertex lines of ΔJ, Vertex (11), *via* Vertex (10), it was found that the fourth attempt gave an $r_{11\cdot9}$, that coincided with the value of $r_{11\cdot9}$, assumed before that trial was made. The shaded area around Joint (11) is the resulting deformation contour, while those around Joint (10) and Joint (12) had already been drawn in the final trial of determining $r_{11\cdot9}$.

A vertical from the end (a) of $r_{10\cdot8}$ to the base of ΔI, at (b), determines the point on the vertex line of ΔI, through which a parallel, (b-d), to the base line is drawn. A 45° line to this newly drawn line from the end (c) of $r_{11\cdot9}$ determines the point (d) from which the second 45° line is drawn to determine $r_{9\cdot11}$ (from (9) to (e)), which is negative in this case. The deformation contour is then drawn; it is shown by shading the edges. All the deformation contours are determined in a similar way. Finally, from the ends of r_{12}

and r_{21}, 45° lines to Member 1-2 are drawn, and it is found that their intersection, (f), practically falls on the parallel line to the base line of Δ A, Vertex (3), determined by drawing a perpendicular to Member 1-2 from the end of r_{31} and thus locating the point of intersection on the vertex line. This was a check on the work.

	6- 4	+ 1.25	— 0.37				

As a final check, equilibrium polygons must be drawn around every joint. Only one, namely, at Joint (9), has been constructed. All the points of application of the S's, except $S_{9\cdot11}$, were found from the deformation contour of Joint (9) and those of the surrounding joints. These S's together with R_9 gave an $S_{9\cdot11}$ that lies only a short distance to the left of the $S_{9\cdot11}$, determined by $r_{9\cdot11}$ and $r_{11\cdot9}$. For the sake of clarity in the drawing the other equilibrium polygons are not shown.

There is a departure from Mao's method in that the f's are determined from a table of r's; Mao completes all the equilibrium polygons.

Mao's Analytical Method.—Plate II gives the complete solution of the problem by means of Mao's analytical method with the rational arrangement of computations.

The explanations given previously (see page 58 and Fig. 48) should serve to clarify the method of procedure here.

There is one departure from the original method; in the ΣM-table for Joint (6), there is an extra row, termed Σ, inserted between Row 6-7 and Row 6-9. The reason for this is to avoid errors. All the coefficients of the x and y and the constant terms for Rows 6-4, 6-5, and 6-7, are added. When Row 6-9 is completed, the negative of the sum of the x's of the Σ and Row 6-9 give the x-coefficient of Row 6-8. In the same manner, the y-coefficient and the k of Row 6-8 are obtained.

In the ΣM_{10} and ΣM_{12}-tables, the Σ is in the last row. An addition of the various columns gives the coefficients for the two simultaneous equations for finding x and y, that is, f_{12} and f_{21}, respectively. The little f-tables around the joints are then filled in, giving the secondary stresses.

Numerical Values.—For purposes of comparison, the amounts of secondary stresses by the foregoing methods have been collected in Table 24.

In determining the nature of the stress of an extreme fiber a clockwise rotation around each joint is made; a bending moment reckoned positive if counterclockwise then produces a tensile stress on the set of fibers first met and a compressive stress on those crossed last. Thus, at Joint (2), Member 2-4 is crossed over from top to bottom. It has a positive bending moment. The top fiber, therefore, has a secondary stress of —1.35 lb. per sq. in. and the bottom fiber one of —1.38 lb. per sq. in. (The difference in the numerical values is due to the respective fibers being 9.33 and 9.54 from the center of gravity of the member.) The resultant stresses of the top and bottom sets of fibers, therefore, would be (— 18.61 — 1.35) lb. per sq. in. and (— 18.61 — 1.38) lb. per sq. in., respectively.

For Member 2-3 at Joint (2) the set of fibers on the right-hand side (side first met) has a secondary stress of — 2.89 lb. per sq. in. and the left-hand side set has one of + 2.89 lb. per sq. in. The primary stress is zero and, therefore, the resultant stresses of the right and left-hand sets are — 2.89 and + 2.89 lb. per sq. in. The primary stresses are also given in Table 24 for information.

3.—Criticism of Methods

This criticism is a process of elimination, starting with Dr. Mao's methods which are believed to be very unsatisfactory.

Mao's Analytical Method.—Dr. Mao worked out the case for a symmetrical load. He was thereby able to solve the problem by using only half the number of triangles in the truss. The solution of the unsymmetrical case (Plate II) makes possible conclusive statements with regard to certain features of this method. It shows how rapidly the coefficients of the x and y and the constant terms, k, increase, as triangle is added to triangle. The coefficients in the U-group on Member 1-2 are of the magnitude 0, 1, or 2, while those in the ΣM_{12}-group range from 213 155.93 to 8 779 438. The question at once presents itself: "What is going to happen in a truss with twice the number of triangles"? These coefficients increase so rapidly, that it is certain they would amount to billions at least. A change of scale might be helpful. At the start the coefficients might be correct to three places of decimals as far as the quarter-point, where all decimals are discarded as far as the half-way point; between the middle and three-quarter points, the last three digits may be neglected, while the remainder of the work may only retain the significant figures up to and including the seventh digit. Now the solution depends on the differences of large numbers, and even if three decimal places were carefully maintained throughout the work, the f-values obtained did not give nearly as fine a check for the $\Sigma M = 0$ equations around the points as some of the other methods. The changes in scale to bring Mao's method within the bounds

of practice in solving the secondary stresses for a truss with only a few more triangles than that used in Plate II, are, therefore, certain to introduce large discrepancies.

Dr. Mao claims that the method is self-checking, that is, that if a computer makes an error, he is almost immediately aware of it. The writer's experience proved the contrary. An error which he made near the beginning of his computations was not discovered until a considerable time afterward and then only by comparing the results with those of the other methods. If there had been no other solution, the error would only have been detected when checking the $\Sigma M = 0$ equations.

This problem concerns a Warren truss with triangular elements. Suppose it had been a truss with subdivided panels, or even the top lateral system of the bridge, shown in Fig. 50. In the former case, some elements other than triangles appear, while all the triangles of the latter case have a vertex in the interior, instead of on the boundary of the frame. To adopt Mao's method to such cases would make an already weak method of smaller value still.

Mao's Graphical Method.—In this case, too, the unsymmetrical loading brings out certain features that were not so pronounced in the symmetrical case treated by Dr. Mao. It must be remembered that Figs. 56 and 57 give only those lines and points that are essential in the final solution. In carrying out the solution, the number of lines that must be drawn is enormous. Consider the problem of finding the base line for Member 5-7. There are required at least three points that must prove to be collinear, before the required line is accurately determined.

An explanation will be given of the steps necessary to arrive at one of these three points. (The process is repeated in its entirety for each of the other two, while each of the many base and vertex lines call for similar determinations.) At the stage where the base line for Member 5-7 is the next line to be determined, the base and vertex lines for the triangles, *A, B, C,* and *D,* have already been determined.

First, assume the reference contour for ΔE, namely, r_{64}, to be zero, and with this value finish a portion of the deformation contour to obtain the corresponding value for r_{65}.

Next, assume some value for r_{56}, and proceed to complete the corresponding deformation contour for Joint (5). Now, draw the vertical line through the end of r_{53} to cut the vertex line of ΔD, and also that of ΔC, as r_{53} is the reference contour for both these triangles. Through each of the two points thus found, draw a parallel to the base line of the corresponding triangle. Returning to the deformation contour at Joint (6), draw a line at 45° from the point, (6) (it being also the end of r_{64} as r_{64} is zero), until it meets the parallel to the base line of ΔD. From this point a line downward at 45° to meet Member 4-6, gives the value of r_{46}. To complete the corresponding deformation contour round Joint (4), draw a line from the end of r_{42}, at 45° upward to the left to cut the parallel to the base line of ΔC, and from this point, a line downward to cut Member 2-4, giving the value of r_{24}. With this the deformation contour around Joint (2) may be completed.

The work is now at the point where the value of the reference contour for ΔB, namely, r_{21}, is known. Draw a line vertically downward through the end of r_{21} to cut the vertex line of ΔB; through this point draw a line parallel to the base line of ΔB. Returning to the deformation contour of Joint (5), draw a line through the end of r_{53} downward at 45° to cut the parallel just found, and from the point of intersection draw a line at 45° upward to the left to cut Member 3-5, giving r_{35}.

This gives all the r's of all the members entering Joint (5) except r_{75}. Making use of the fact that $3\ f_{5n} = 2\ r_{5n} + r_{n5}$, determine the points on Members 5-3, 5-2, 5-4, and 5-6, that are distant $3\ f_{53}$, $3\ f_{52}$, $3\ f_{54}$, and $3\ f_{56}$, respectively, from Joint (5). Draw the S's through these points and complete the equilibrium polygon. S_{57} is regarded as the resultant of R_5, S_{53}, S_{52}, S_{54}, and S_{56}. Its distance from Joint (5) along Member 5-7 is $3\ f_{57}$.

Now, $r_{75} = 3\ f_{57} - 2\ r_{57}$, and as r_{57} was assumed at the start, the value of r_{75} is known. Draw a line through the end of r_{57} downward to the right and at 45°; draw another line through the end of r_{75} downward to the left and at 45 degrees. The point of intersection is the first point on the required base line.

It is at once evident that the amount of labor is prodigious, while the likelihood of error in the process may be the cause of many hours being wasted. Of course, where two or three members enter a joint, the process of determining the base and vertex lines, although complicated, is not as extended as that just explained.

In applying this graphical method, the number of lines becomes so great that the draftsman becomes lost. The natural thing to do would be to erase those lines that had been used to find a point and would not be used again. No erasures should be made, however, until the base line or the vertex line has been definitely found, otherwise the three points may be non-collinear and the lines may be lost from which these points were found; this would necessitate starting the problem of finding that particular base or vertex line from the very beginning.

There is no doubt that if all the checks are carefully carried out, Mao's graphical method will be correct, as the drawing proceeds, and will give results that are surprisingly accurate. However, it is not to be recommended. In the first place, it requires a large scale for reasonable accuracy; the result is an unwieldy drawing. Again, it requires ingenuity to adapt it to the solution of trusses with subdivided panels, for, as it is now, it cannot be so used. Thirdly, the labor involved to arrive at the "base" and "vertex" lines is excessive, and because of the many repetitions of the same process, is bound to become extremely monotonous. Finally, any graphical method is objectionable in the drafting-room, as a complete and thorough check by a second man requires an entirely new solution of the whole problem.

Ritter's Graphical Method.—This method entails much more than appears in Fig. 53. In this case, as in Mao's graphical method, the great number of lines that were required to arrive at the final solution shown, have been erased. The method gives reasonably accurate results. Bridge engineers, however,

would prefer an analytical method, which can be carried to any degree of accuracy. It may be said in favor of Ritter's method, that it may be checked by drawing a fresh set of equilibrium polygons. The writer, however, has an objection that eliminates Ritter's method. When the influence lines for the secondary stresses are required, and several conditions of loading are analyzed, Ritter's method cannot be used as advantageously as that of Manderla.

Müller-Breslau's and Mohr's "Elastic Weight" Methods.—Both these methods are to be discarded for the simple reason that the derivation of the $(4n\text{-}6)$ unknown quantities from a set of $(4n\text{-}6)$ simultaneous equations requires many places of decimals for reasonably accurate results. During the process of elimination, errors are likely to enter and cannot be detected until the $\Sigma M = 0$ checks for the joints are performed. Engineers have been bitterly opposed to methods that do not contain some checking features; how any one, therefore, can advocate these methods is difficult to understand.

Mohr's Semi-Graphical Method.—This method is better than all the preceding methods, when the solution of the simultaneous equations is performed by the method of Gauss' normal equations. Its accuracy depends on the accuracy with which the Williot diagram is drawn. Errors are liable to enter in the determination of the signs of the ρ's in the diagram, but, as the diagram is clear and contains few lines, it may easily be checked independently. It has the advantage over Manderla's method in that the changes of slope of the various members are at once found and, therefore, can be readily tested in practice.

Manderla's Method.—On comparison with the standard (Mohr's elastic weight method, carried to ten places of decimals) Mohr's semi-graphical and Manderla's methods give results that are close (Table 24). The calculations of these methods involve only three decimal places. In the matter of checking the computations, analytical methods are generally preferred to graphical. The writer personally much prefers Manderla's method to that of Mohr and has found that it could be used advantageously in the determination of influence lines.

In the case of plane frames that are not entirely composed of triangular elements Manderla's method shows itself more advantageous than any other. There is one exception, with rectangular frames that suffer bending but no change in the length of their members, Mohr's elastic weight method may be used to advantage.

Although Manderla's method still retains the features that made scientists anxious to improve on it, the writer's investigations have convinced him that none of the later ones is superior. There is a point of great importance that seems to be overlooked by many; the very fact that Manderla was able to obtain a set of relations between a portion of the unknown quantities (the number being the smallest possible, namely, the number of the joints) counts heavily in favor of that method.

The writer would urge that Gauss' theory of normal equations, or Turneaure's method of elimination, be used in every solution. With regard to the former, the instructions are put in such a manner that an inexperienced

engineer can carry out the solution of the unknown τ's to any desired degree of accuracy by means of a calculating machine; if he assures himself of the check at every stage of the solution, he cannot go wrong. The method is superior to that by substitution, where many trials are performed before any reasonable result is found, and where the additions and subtractions that are continually carried out on papers at the side are most annoying. The very directness of Gauss' method, where the object is definitely in view, ought to appeal to every one. Finally, the process of multiplying the equations by quantities far less than unity never allows the coefficients to become large. The solution may be made correct to five decimal places almost as easily as to three.

PART IV.—SOLUTION OF SECONDARY STRESSES BY INFLUENCE LINES

1.—Introduction

The stresses that occur in a bridge, subjected to (1) dead load and (2) dead load plus live load, will now be investigated. The bridge shown in Plate I and Figs. 49 and 50 will again be used. As symmetry is maintained about the longitudinal central vertical plane under both conditions of loading, it will be possible to use the same set of influence lines in each case. This set will tell when a certain member is taxed most heavily, what fiber suffers most, and what is the value of the stress in it at the instant.

To make the problem complete, it would be necessary to analyze the bridge for wind load and traction also, and combine the resulting solutions with those found in this paper to get the absolute maximum.

A certain amount of work has been omitted in order to save space. For example, only the equations in Section 2 resulting from 1 000 lb. at Panel Point (7) and 3 000 lb. at Panel Point (11), are reproduced, the work of obtaining these being exactly similar to that found in Tables 1 to 5, inclusive.

2.—Influence Lines for the Bridge Trusses

Load of 1 Kip at Panel Point (7).—Tables are prepared corresponding to Tables 2, 3, and 4, for use in forming the equations. As there is symmetry about the central vertical member, 6-7, no bending moments are found in it, while certain relations between the τ's reduce the number of equations to be solved to five. If the equations for Joints (1), (2), (3), (4), and (5) are written, it will be found that τ_6 and τ_7 enter into the last two equations. As there can be no bending in Member 6-7,

$$\tau_{67} = \tau_{76} = 0$$

Table 3 gives:

$$\tau_{67} = \tau_6 + 24.61 + 35.38$$

and,

$$\tau_{76} = \tau_7 - 110.92$$

whence,

$$\tau_6 = 59.99 \quad \text{and} \quad \tau_7 = +110.92$$

Finally, substituting these values in Equations (4) and (5) the equations for joints:

Joint (1)... $+ 15.930\,\tau_1 + 5.464\,\tau_2 + 2.501\,\tau_3 + 27.96 = 0$

Joint (2)... $+ 30.806\,\tau_2 + 7.951\,\tau_4 + 1.685\,\tau_5 + 0.303\,\tau_3 + 5.464\,\tau_1 - 2.58 = 0$

Joint (3)... $+ 10.610\,\tau_3 + 2.501\,\tau_1 + 0.303\,\tau_2 + 2.501\,\tau_5 - 25.50 = 0$

Joint (4)... $+ 32.184\,\tau_4 + 0.190\,\tau_5 + 7.951\,\tau_2 + 997.68 = 0$

Joint (5)... $+ 19.528\,\tau_5 + 2.501\,\tau_3 + 1.685\,\tau_2 + 0.190\,\tau_4 + 190.82 = 0$

Load of 1½ *Kips at Panel Point* (*9*).—This is the work completed on Fig. 51 and Tables 1 to 7.

Load of 3 Kips at Panel Point (*11*).—A process similar to that followed in the preceding case gives:

Joint (1)... $+ 15.930\,\tau_1 + 5.464\,\tau_2 + 2.501\,\tau_3 + 27.96 = 0$

Joint (2)... $+ 30.806\,\tau_2 + 7.951\,\tau_4 + 1.685\,\tau_5 + 0.303\,\tau_3 + 5.464\,\tau_1 - 2.58 = 0$

Joint (3)... $+ 10.610\,\tau_3 + 2.501\,\tau_1 + 0.303\,\tau_2 + 2.501\,\tau_5 - 25.50 = 0$

Joint (4)... $+ 32.184\,\tau_4 + 7.951\,\tau_6 + 0.190\,\tau_5 + 7.951\,\tau_2 + 828.72 = 0$

Joint (5)... $+ 19.528\,\tau_5 + 2.501\,\tau_3 + 1.685\,\tau_2 + 0.190\,\tau_4 + 1.800\,\tau_6 + 3.588\,\tau_7 - 610.88 = 0$

Joint (6)... $+ 39.610\,\tau_6 + 7.951\,\tau_8 + 1.800\,\tau_9 + 0.303\,\tau_7 + 1.800\,\tau_5 + 7.951\tau_4 + 842.42 = 0$

Joint (7)... $+ 14.958\,\tau_7 + 3.588\,\tau_5 + 0.303\,\tau_6 + 3.588\,\tau_9 - 443.04 = 0$

Joint (8)... $+ 32.184\,\tau_8 + 7.951\,\tau_{10} + 0.190\,\tau_9 + 7.951\,\tau_6 + 2\,619.39 = 0$

Joint (9)... $+ 19.528\,\tau_9 + 3.588\,\tau_7 + 1.800\,\tau_6 + 0.190\,\tau_8 + 1.685\,\tau_{10} + 2.501\,\tau_{11} + 227.60 = 0$

Joint (10).. $+ 30.806\,\tau_{10} + 5.464\,\tau_{12} + 0.303\,\tau_{11} + 1.685\,\tau_9 + 7.951\,\tau_8 + 5271.52 = 0$

Joint (11).. $+ 10.610\,\tau_{11} + 2.501\,\tau_9 + 0.303\,\tau_{10} + 2.501\,\tau_{12} - 2\,911.27 = 0$

Joint (12).. $+ 15.930\,\tau_{12} + 2.501\,\tau_{11} + 5.464\,\tau_{10} + 1\,034.14 = 0$

Simultaneous Equations.—It will be noticed that the first three equations of all the sets are identical, while the equations for Joints (1), (2), (3), (4), (5), and (7) are the same for the last two sets. These facts are used in the solutions, Table 25. The blank spaces could be filled with the quantities in the corresponding spaces of the preceding cases; it is evident that a certain amount of work for Case II was already done in solving Case I, while an even larger amount is duplicated in Cases II and III. The solution of such sets of equations is exceedingly easy and once all the coefficients in the τ-columns are found, any extra solution offers little trouble. The checks that occur all through the work make it impossible for a computer to go wrong in that part of the problem.

Table of τ-Values and Bending Moments.—A table similar to Table 6 can now be drawn up for the three cases, after which the $\Sigma M = 0$ test must be fulfilled for every joint.

Table of Secondary Stresses.—The bending moments found for Cases II and III are for 1 500 lb. and 3 000 lb., respectively. To obtain influence lines, the two sets are divided by 1.5 and 3, respectively. The resulting quantities are found in Table 26. The secondary stresses are found by multiplying the bending moments by $\frac{c}{I}$, in which c is the extreme fiber distance, and I the moment of inertia of the member under consideration.

Influence Lines.—Figs. 58 to 68 contain the influence lines for the primary stresses and those secondary stresses that are due to the rigidity of the joints in the plane of the truss.

Consider the end chord, 1-2 (Fig. 58). Compressive primary stresses are drawn downward from a base line equal in length to the span of the bridge, while tensile primary stresses are drawn upward. The secondary stresses are drawn in just the reverse way, that is, compressive upward and tensile downward. To determine end effects, plot a set of lines for each end. The primary stress influence line, therefore, is drawn twice. Turning to Table 26, note that the primary stress in Member 1-2, is — 12.99 lb. per sq. in. for a load of 1 000 lb. at Joint (7), — 8.66 lb. per sq. in. for a load of 1 000 lb. at Joint (9), and — 4.33 lb. per sq. in. for a load of 1 000 lb. at Joint (11).

Continued).

Now, when 1 000 lb. act at Joint (5), the effect on Member 1-2 is exactly the same as the effect of 1 000 lb. at Joint (9) on Member 10-12. From Table 26, this is — 17.32 lb. per sq. in. Finally, when 1 000 lb. act at Joint (3), the effect on Member 1-2 is exactly the same as the effect of 1 000 lb. at Joint (11) on Member 10-12, or — 21.65 lb. per sq. in.

The secondary stresses in Member 1-2 for End (1), are — 0.46, — 0.27, and — 0.13 lb. per sq. in., respectively, for the outside fiber stress, when the 1 000-lb. load is at Joints (7), (9), and (11), respectively, and + 0.47, + 0.28, and + 0.14 lb., respectively, for the inside fibers.

Again, 1 000 lb. acting at Joint (5) has exactly the same effect on End (1) as 1 000 lb. acting at Joint (9) has on End (12) of Member 12-10. It should be remembered that all the tabulations are for clockwise rotations around the joints, hence, the first set of fibers of Member 1-2, at End (1) corresponds to the last set of fibers of Member 12-10, at End (12). Therefore, take — 0.608 lb. per sq. in., found in Row 12-10, as the secondary stress in the outside fibers of End (1), when the 1 000 lb. act at Joint (5). The remainder follows in exactly the same way.

The reason for the reverse manner of representing the two kinds of stress is now evident; a glance at the four numbers that lie between the primary and secondary stress lines shows that the very maximum may happen to Member 1-2, when the bridge is fully loaded, and that it is the outside fibers of End (1), that are taxed more heavily than any of the three remaining sets.

3.—Influence Lines for the Top Lateral System

The top lateral system forms a plane framework that has secondary stresses induced under either dead load or a combination of dead and live loads. The frame is considered complete from Joint (2) to Joint (10) of the bridge. Theoretically, the end portals contribute to the secondary stresses; their effect on the top lateral system, however, differs little from that found by reckoning the web-plates of the end portals as the closing members of the frame.

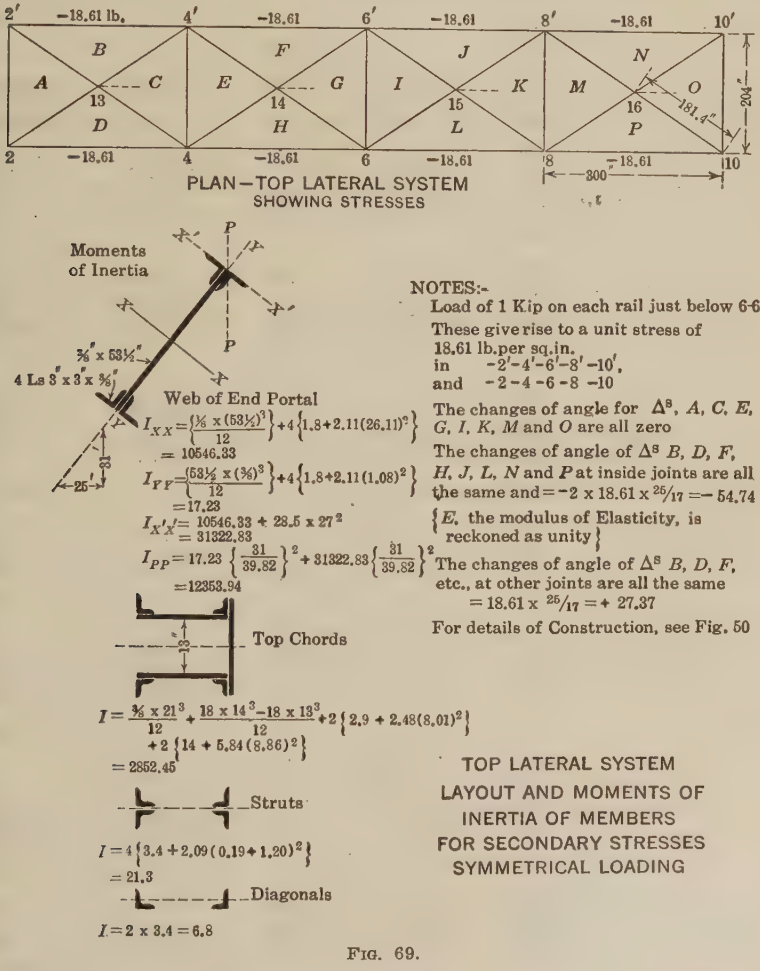

Fig. 69.

When there are two 1 000-lb. loads directly below Member 6-6′, Fig. 69, and symmetrical about the longitudinal center line, the unit stresses induced in the top chords are uniform and equal to — 18.61 lb. per sq. in. Fig. 69 and Tables 27 to 29 represent the solution for this case. The determination of the new set of moments of inertia, characteristic of a horizontal frame, is to be noted.

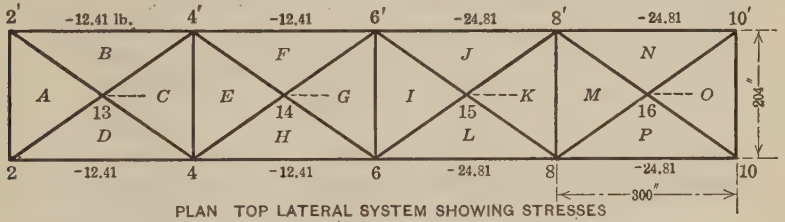
When there are two 1 000-lb. loads directly below Member 8-8′, Fig. 70, symmetrical about the longitudinal center line, the unit stresses in Members 2-4, 4-6, 2′-4′, and 4′-6′, are the same and equal to — 12.41 lb. per sq. in., while the unit stresses in Members 6-8, 8-10, 6′-8′, and 8′-10′, are the same and equal to — 24.81 lb. per sq. in. Fig. 70 and Tables 30 to 33 represent the solution for this case.



PLAN TOP LATERAL SYSTEM SHOWING STRESSES

NOTES:

Load of 1 Kip on each rail just below 8 - 8′.

The changes of angle in all the Δs A, C, E, G, I, K, M and O are all zero.

The changes of angle of B_2', B_4', F_4', F_6', D_2, D_4', H_4 and H_6 are each + 18.25.

The changes of angle of J_6', J_8', N_8', N_{10}', L_6, L_8', P_8 and P_{10} are each + 36.49.

The changes of angle of B_{13}, D_{13}, F_{14} and H_{14} are each - 36.50; those of J_{15}, L_{15}', N_{16}', P_{16} are each - 72.98.

For details of construction see Fig. 50.

For Moments of Inertia of Members see Fig. 69.

TOP LATERAL SYSTEM LAYOUT FOR OBTAINING SECONDARY STRESSES UNSYMMETRICAL LOADING

FIG. 70.

When there are two 1 000-lb. loads directly below Member 10-10′, symmetrical about the longitudinal center line, the unit stresses in the top chords are exactly one-half those of the former case (the 1 000-lb. loads directly below Member 8-8′). The previous solution therefore determines the effect of loads directly below Members 2-2′ and 10-10′, as the bending moments and secondary stresses are just one-half what they are when the loads are directly below Member 4-4′ and Member 8-8′, respectively.

Therefore, only two sets of solutions are required, which are extremely easy, as may be noted. The ease with which Manderla's method of solution is used when there are interior joints is worthy of note.

In this analysis for the top lateral system, the influence lines for Members 2-4 and 4-6 are the only ones required for the chord members, as the loading

TABLE 28.—(*Continued*).

FROM SYMMETRY:

$$\begin{aligned}
\tau_8' &= \tau_{8'\cdot 10'} = -\tau_{4'2'} \\
&= -(\tau_4' + 54.74) \\
&= -\tau_4' - 54.74, \\
\tau_8 &= \tau_{86} = -\tau_{46} \\
&= -\tau_4 - 54.74, \\
\tau_{15} &= \tau_{15\cdot 8} = -\tau_{14\cdot 4} = -\tau_{14} + 54.74, \\
\tau_{24} &= -\tau_{2'4'} \\
&\text{Therefore } \tau_{2'} = -\tau_2 - 27.37, \\
\tau_{42} &= -\tau_{4'2'} \\
&\text{Therefore } \tau_4 = -\tau_{4'} - 54.74, \\
\tau_{6\cdot 4} &= -\tau_{6'4'} \\
&\text{Therefore } \tau_6 = -\tau_{6'} - 54.74.
\end{aligned}$$

SOLUTION:

$$\begin{aligned}
&2.-140.208\,\tau_2 + 60.559\,(-\tau_2 - 27.37) + 0.037\,\tau_{13} + 9.508\,\tau_4 + 2\,175.943 = 0 \\
&13.-0.296\,\tau_{13} + 0.037\,\tau_4 + 0.037\,\tau_2 + 0.037\,(-\tau_2 - 27.37) + 0.037\,(-\tau_4 - 54.74) - 13.165 = 0 \\
&4.-38.388\,\tau_4 + 9\,508\,\tau_2 + 0.037\,\tau_{13} + 0.104\,(-\tau_4 - 54.74) + 0.037\,\tau_{14} + 9.508\,\tau_6 + 1\,311.735 = 0 \\
&14.-0.296\,\tau_{14} + 0.037\,\tau_6 + 0.037\,\tau_4 + 0.037\,(-\tau_4 - 54.74) + 0.037\,(-\tau_6 - 54.74) - 12.152 = 0 \\
&6.-38.388\,\tau_6 + 9.508\,\tau_4 + 0.037\,\tau_{14} + 0.104\,(-\tau_6 - 57.74) + 0.037\,(-\tau_{14} + 54.74) \\
&\qquad + 9.508\,(-\tau_4 - 54.74) + 1\,571.969 = 0
\end{aligned}$$

that is.

$$\begin{aligned}
&2. + 79.649\,\tau_2 + 0.037\,\tau_{13} + 9.508\,\tau_4 + 518.443 = 0 \\
&13. + 0.296\,\tau_{13} - 16.203 = 0 \\
&4. + 38.284\,\tau_4 + 9.508\,\tau_2 + 0.037\,\tau_{13} + 0.037\,\tau_{14} + 9.508\,\tau_6 + 1\,306.042 = 0 \\
&14. + 0.296\,\tau_{14} - 16.203 = 0 \\
&6. + 38.284\,\tau_6 + 1\,047.834 = 0
\end{aligned}$$

$$\begin{aligned}
&\text{Therefore } \tau_{13} = \tau_{14} = +54.74, \\
&\qquad \tau_6 = -27.37, \\
&\text{and } +79.649\,\tau_2 + 9.508\,\tau_4 + 520.468 = 0 \\
&\qquad +9.508\,\tau_2 + 38.284\,\tau_4 + 1\,049.859 = 0, \\
&\text{Therefore } \tau_4 = -26.588, \\
&\qquad \tau_2 = -3.361.
\end{aligned}$$

$$\text{Therefore } \begin{cases}
\tau_2 = -3.361 \\
\tau_4 = -26.588 \\
\tau_6 = -27.370 \\
\tau_{13} = +54.740 \\
\tau_{14} = +54.740 \\
\tau_{2'} = -24.009 \\
\tau_{4'} = -28.152 \\
\tau_{6'} = -27.370 \\
\tau_{15} = \ldots\ldots \\
\tau_8 = -28.152 \\
\tau_{8'} = -26.588
\end{cases}$$

is symmetrical about the longitudinal center line. If necessary, the influence lines for the struts and diagonals could easily be drawn. The influence lines for Members 2-4 and 4-6 are given in Figs. 71 and 72. They have been purposely drawn for bending moments, and not for secondary stresses. From Fig. 69 it is seen that the extreme fiber distances of the cover-plate and the bottom angles of the chords are, respectively, 10.5 in. and 12 in. from the neutral plane under consideration. As the moment at the end of a member is numerically the same, no matter which extreme fiber distance is considered, an influence line for bending moment can be converted at once into the secondary stress influence line for a particular extreme fiber by suitably changing the scale. Hence, by multiplying the quantities for End (4) by $\pm \frac{10.5}{2\,852.45}$, the secondary stress influence lines for the extreme fibers of the cover-plate are obtained, and if by $\pm \frac{12}{2\,852.45}$, those for the extreme fibers of the bottom angles.

TABLE 29.—SECONDARY STRESSES IN TOP LATERAL, ETC. VALUES OF MOMENTS.

2'	$\tau_{2'4'} = -24.009 + 27.370$	$M_{2'4'} = 19.016 (-48.018 + 26.588) = -407.51$

Tables 29 and 33 permit the construction of the influence lines as follows: When the loads are below Member 6-6′, $M_{46} = +550.21$ and $M_{64} = -505.60$ in-lb. When the loads are below Member 8-8′, $M_{46} = +320.06$ and $M_{64} = -504.38$ in-lb. When the loads are below Member 10-10′, these last two quantities are halved, giving +160.03 and −252.19, respectively. When the loads are below Member 4-4′, the effects on End (4) and End (6) of Member 4-6 are the same as the effects on End (8) and End (6), respectively, of Member 8-6 when the loads are situated below Member 8-8′. Here, there is a slight variation, depending on the convention of signs. M_{86} is given as −785.57 in-lb., Table 33, that is, a bending moment that is acting in a clockwise direction around Joint (8); the corresponding one around Joint (4), therefore, must be counterclockwise and reckoned as +785.57 in-lb. The remaining influence lines can be easily deduced.

4.—Influence Lines for Cross-Frame 6-6′-7′-7

The effect of the slender angles that extend from the top lateral strut to the vertical posts is neglected; the secondary stresses due to them are extremely small. Therefore, the problem concerns a rectangular frame, as shown in Fig. 73. Consider the unsymmetrical case of a load on one rail only; not only will this determine the best method under the worst conditions, but it may easily be extended to take into account wind forces.

693.894

$+5\,116.190$

From Symmetry:

$$\left.\begin{aligned}\tau_2' &= -\tau_2 - 18.25\\ \tau_4' &= -\tau_4 - 36.50\\ \tau_6' &= -\tau_6 - 54.74\\ \tau_8' &= -\tau_8 - 72.98\end{aligned}\right\}$$
$$\tau_{10}' = -\tau_{10} - 36.49$$

Equation (2′) becomes:

$+140.208\,(-\tau_2-18.25)+9.508\,(-\tau_4-36.50)+0.037\,\tau_{13}+60.559\,\tau_2+2\,557.446=0,$

that is, $+79.649\,\tau_2+9.508\,\tau_4-0.037\,\tau_{13}+348.392=0.$

Equation (2) becomes:

$+79.649\,\tau_2+9.508\,\tau_4+0.037\,\tau_{13}+345.692=0.$

Combined:

$+79.649\,\tau_2+9.508\,\tau_4+347.042=0.$

Similarly, Equations (4′) and (4) give:

$+38.284\,\tau_4+9.508\,\tau_6+9.508\,\tau_2+873.554=0,$

Equations (6′) and (6) give:

$+38.284\,\tau_6+9.508\,\tau_8+9.508\,\tau_4+1\,393.927=0,$

Equations (8′) and (8) give:

$+38.284\,\tau_8+9.508\,\tau_{10}+9.508\,\tau_6+1\,920.151=0,$

Equations (10′) and (10) give:

$+79.649\,\tau_{10}+9.508\,\tau_8+2\,909.092=0.$

		—2.3948	—16.48813	—23.29260	—36.37862	—32.18130		

Equation (13) gives:

$$+0.296\,\tau_{13} - 8.779 - 0.037 \times 18.25 - 0.037 \times 36.50 = 0,$$

that is,

$$+0.296\,\tau_{13} - 10.805 = 0,$$

$$\tau_{13} = +36.50.$$

Equation (14) gives:

$$+0.296\,\tau_{14} - 7.428 - 0.037 \times 91.24 = 0,$$

$$\tau_{14} = +36.50.$$

Equation (15) gives:

$$+0.296\,\tau_{15} - 16.877 - 0.037 \times 127.72 = 0,$$

$$\tau_{15} = +72.98.$$

Equation (16) gives:

$$+0.296\,\tau_{16} - 17.552 - 0.037 \times 109.47 = 0,$$

$$\tau_{16} = +72.98.$$

TABLE 33.—Secondary Stresses in Top Lateral System Due to Dead and Unsymmetrical Live Loads. Values of Moments.

As the angles at the joints remain right angles at all times, because of the rigidity of the joints in the Plane 6-6′-7′-7, the posts suffer bending at their lower ends when the floor-beam is loaded. The shape of the frame is then somewhat like the dotted part of Fig. 74.

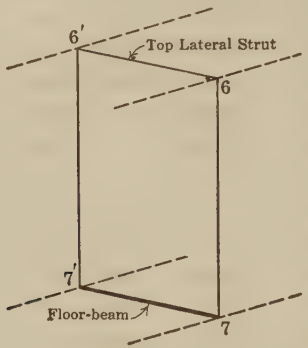

FIG. 73.

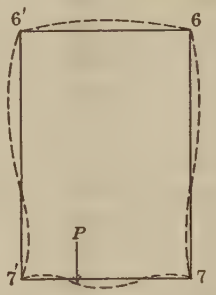

FIG. 74.

It must be remembered that no direct stresses enter the frame, for all the loads are taken care of by the diagonals and bottom chords that meet in Joints (7) and (7′). The analyses of Table 2 show that the primary stresses in Members 6-7 and 6′-7′ for dead and live loads are always zero.

There are three ways of attacking the problem, namely, the method of least work, Mohr's elastic weight method, and Batho's slope-deflection method. The first method will be omitted as it is unnecessarily long.

Mohr's Method.—The principles underlying this method are exactly those of the method for trusses, already described (see page 31), and, therefore, need no explanation. E is again regarded as unity.

From the dimensions of the rectangular frame, Fig. 75,

$$I_{6'\text{-}6} = 529 \text{ in.}^4$$

and

$$l_{6'\text{-}6} = 204 \text{ in.} \quad \therefore \beta_{6'\text{-}6} = \frac{204}{2 \times 529} = 0.1928. \text{ (See Equation (78))}$$

$$I_{6'\text{-}7'} = I_{6\text{-}7} = 548 \text{ in.}^4$$

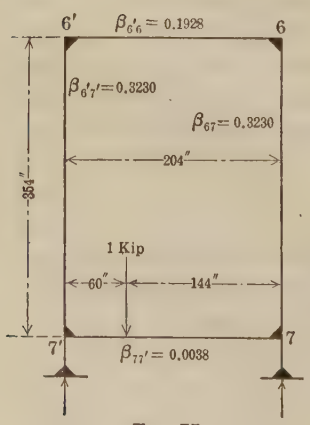

FIG. 75.

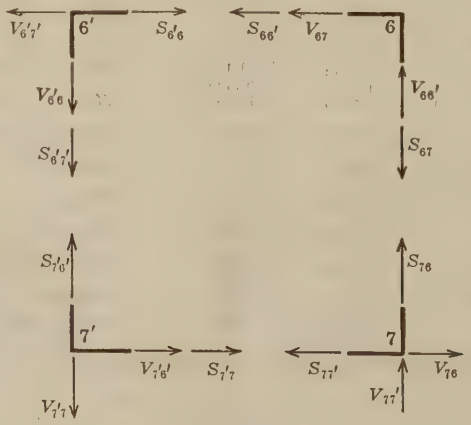

FIG. 76.

and,

$$l_{6'\text{-}7'} = l_{6\text{-}7} = 354 \text{ in.} \therefore \beta_{6'\text{-}7'} = \beta_{6\text{-}7} = \frac{354}{2 \times 548} = 0.3230$$

$$I_{7\text{-}7'} = 27\ 020 \text{ in.}^4$$

and,

$$l_{7\text{-}7'} = 204 \text{ in.} \therefore \beta_{7\text{-}7'} = \frac{204}{2 \times 27\ 020} = 0.0038$$

If the equilibrium of the joints is considered, as represented in Fig. 76, certain shearing forces, V, are induced at the joints due to the end bending moments resulting from the rigidity of the joints. These bending moments, eight in all, are the unknowns to be determined. $M_{6'\,7'}$ and $M_{7'\,6'}$ of Member 6′-7′ give rise to the two equal and opposite shearing forces, $V_{6'\,7'}$ and $V_{7'\,6'}$ at Joint (6′) and Joint (7′), respectively. In the sense that they are drawn, positive bending moments are calculated clockwise (see Fig. 5). All the other V's are inserted in the same manner. Finally, internal direct stresses, S, are induced.

For equilibrium of joints under direct stresses:

$$\left.\begin{array}{llll} (a)\ S_{6'\text{-}7'} = +\ V_{7\text{-}7'} & ; & (b)\ S_{6'\text{-}7'} = -\ V_{6'\text{-}6} \\ (c)\ S_{6'\text{-}6} = +\ V_{7'\text{-}6'} & ; & (d)\ S_{6'\text{-}6} = -\ V_{6\text{-}7} \\ (e)\ S_{6\text{-}7} = +\ V_{6'\text{-}6} & ; & (f)\ S_{6\text{-}7} = -\ V_{7\text{-}7'} \\ (g)\ S_{7\text{-}7'} = +\ V_{6\text{-}7} & ; & (h)\ S_{7\text{-}7'} = -\ V_{7'\text{-}6'} \end{array}\right\} \quad \ldots\ldots\ldots (101)$$

For equilibrium of the joints under bending moments:

$$\left.\begin{array}{ll} (a)\ M_{7'\text{-}7} = -\ M_{7'\text{-}6'} \\ (b)\ M_{6'\text{-}7'} = -\ M_{6'\text{-}6} \\ (c)\ M_{6\text{-}6'} = -\ M_{6\text{-}7} \\ (d)\ M_{7\text{-}6} = -\ M_{7\text{-}7'} \end{array}\right\} \quad \ldots\ldots\ldots\ldots\ldots\ldots (102)$$

Also,

$$\left.\begin{array}{ll} (a)\ V_{7'\text{-}6'} = V_{6'\text{-}7'} = \dfrac{M_{7'\text{-}6'} + M_{6'\text{-}7'}}{354} \\ (b)\ V_{6'\text{-}6} = V_{6\text{-}6'} = \dfrac{M_{6'\text{-}6} + M_{6\text{-}6'}}{204} \\ (c)\ V_{6\text{-}7} = V_{7\text{-}6} = \dfrac{M_{6\text{-}7} + M_{7\text{-}6}}{354} \\ (d)\ V_{7\text{-}7'} = V_{7'\text{-}7} = \dfrac{M_{7\text{-}7'} + M_{7'\text{-}7}}{204} \end{array}\right\} \quad \ldots\ldots\ldots\ldots (103)$$

This is easily proved as follows: Let two end moments, M_{ab}, M_{ba}, act on Member a-b, Fig. 77, and let the two end shears be V_{ab} and V_{ba}.

For equilibrium in a vertical direction, $V_{ab} = V_{ba}$. Also, $M_x = M_{ab} - V_{ab} \cdot x$.

When $x = l$,

$$M_{ba} + M_{ab} - V_{ab} \cdot l = 0$$

or,

$$V_{ab} = V_{ba} = \frac{M_{ab} + M_{ba}}{l}$$

Consider now the elastic weights that are involved in the problem (see Fig. 79):

$$\left.\begin{aligned}
&(a)\ \phi_{7'\text{-}6'} = +\beta_{7'\text{-}6'} \cdot M_{7'\text{-}6'} = +0.3230\ M_{7'\text{-}6'}\\
&(b)\ \phi_{6'\text{-}7'} = -\beta_{7'\text{-}6'} \cdot M_{6'\,7'} = -0.3230\ M_{6'\text{-}7'}\\
&(c)\ \phi_{6'\text{-}6} = +0.1928\ M_{6'\text{-}6}\\
&(d)\ \phi_{6\,6'} = -0.1928\ M_{6\text{-}6'}\\
&(e)\ \phi_{6\text{-}7} = +0.3230\ M_{6\text{-}7}\\
&(f)\ \phi_{7\text{-}6} = -0.3230\ M_{7\text{-}6}\\
&(g)\ \phi_{7\text{-}7'} = +0.0038\ M_{7\,7'}\\
&(h)\ \phi_{7'\text{-}7} = -0.0038\ M_{7'\text{-}7}
\end{aligned}\right\} \quad \ldots\ldots\ldots (104)$$

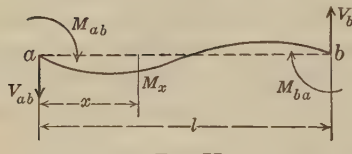

FIG. 77.

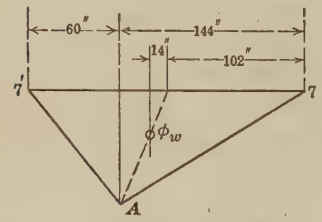

FIG. 78.

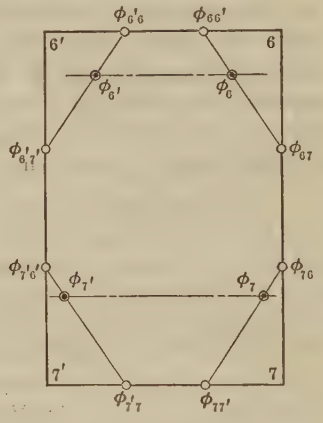

FIG. 79.

These eight quantities may be replaced by four elastic weights, the positions of which are determined by:

$$\left.\begin{aligned}
&\phi_{7'\text{-}6'}\ \phi_{7'} : \phi_{7'}\ \phi_{7'\text{-}7} = 0.0038 : 0.3230\\
&\phi_{6'\text{-}7'}\ \phi_{6'} : \phi_{6'}\ \phi_{6'\text{-}6} = 0.1928 : 0.3230\\
&\phi_{6\text{-}6'}\ \phi_{6} : \phi_{6}\ \phi_{6\text{-}7} = 0.3230 : 0.1928\\
&\phi_{7\text{-}6}\ \phi_{7} : \phi_{7}\ \phi_{7\text{-}7'} = 0.0038 : 0.3230
\end{aligned}\right\} \quad \ldots\ldots\ldots\ldots (105)$$

and the weights of which are:

$$\left.\begin{aligned}
\phi_{7'} &= +0.3268\ M_{7'\text{-}6'}\\
\phi_{6'} &= +0.5158\ M_{6'\text{-}6}\\
\phi_{6} &= +0.5158\ M_{6\text{-}7}\\
\phi_{7} &= +0.3268\ M_{7\text{-}7'}
\end{aligned}\right\} \quad \ldots\ldots\ldots\ldots\ldots\ldots (106)$$

The four quantities are at the corners of a trapezoid the parallel sides of which, $\phi_{6'}\text{-}\phi_6$ and $\phi_{7}\text{-}\phi_{7'}$, have the lengths.

$$\phi_{6'}\text{-}\phi_6 = 68 + \frac{3230}{5158} \times 136 = 153.16 \text{ in.}$$

and,

$$\phi_{7'}\text{-}\phi_7 = 68 + \frac{3230}{3268} \times 136 = 202.42 \text{ in.}$$

also, the height of which is:

$$+ 354 = \frac{3230}{3268} \times 118 - \frac{3230}{5158} \times 118 = 163.48 \text{ in.}$$

To account for the elastic weight due to the bending moment of 1 kip on Member 7-7′, 60 in. from Point (7′) (see Fig. 78), the bending moment area is a triangle, the height of which is $\frac{1\,000 \times 60 \times 144}{204}$ in-lb.

The area, therefore, is,

$$\frac{1}{2} \times 204 \times \frac{1\,000 \times 60 \times 144}{204} = (12\,000 \times 360) \text{ in-sq-lb.}$$

As,

$$I_{7\text{-}7'} = 27\,020 \text{ in.}$$

$$\phi_w = + \frac{12\,000 \times 360}{27\,020} = + 159.88$$

The point of application of ϕ_w is in Member 7′-7, distant 88 in. from Point (7′), this being the distance of the center of gravity of $\Delta\, 7'\, A\, 7$ from Point (7′).

The elastic chain then is replaced by the system of weights shown in Fig. 80.

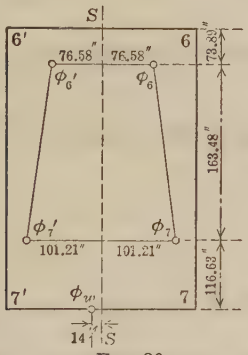

Fig. 80.

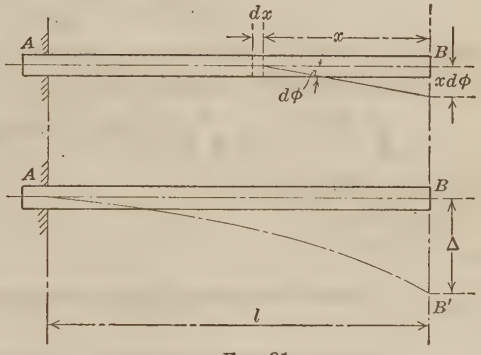

Fig. 81.

Taking moments about $\phi_{6'}$-ϕ_6, ϕ_7-$\phi_{7'}$, s-s;

$$+ (0.3268\, M_{7'\text{-}6'} \times 163.48) + (0.3268\, M_{7\text{-}7'} \times 163.48) + (159.88 \times 280.11) = 0 \quad \ldots\ldots (107)$$

$$+ (0.5158\, M_{6'\text{-}6} \times 163.48) + (5\,158\, M_{6\text{-}7} \times 163.48) - (159.88 \times 116.63) = 0 \quad \ldots\ldots (108)$$

$$+ (0.5158\, M_{6'\text{-}6} \times 76.58) - (0.5158\, M_{6\text{-}7} \times 76.58) + (0.3268\, M_{7'\text{-}6'} \times 101.21) - (0.3268\, M_{7\text{-}7'} \times 101.21) + 159.88 \times 14 = 0 \quad \ldots\ldots (109)$$

Also, Equations (101) and (102) give

$$V_{7'\text{-}7} + V_{6'\text{-}6} = 0$$

or,

$$\frac{M_{7\text{-}7'} + M_{7'\text{-}7}}{204} + \frac{M_{6'\text{-}6} + M_{6\text{-}6'}}{204} = 0$$

that is,

$$M_{7\text{-}7'} + M_{7'\text{-}7} + M_{6'\text{-}6} + M_{6\text{-}6'} = 0$$

that is,

$$M_{7\text{-}7'} - M_{7'\text{-}6'} + M_{6'\text{-}6} - M_{6\text{-}7} = 0 \quad \ldots\ldots (110)$$

The four equations, (107), (108), (109), and (110), contain the four unknowns, $M_{7'\text{-}6'}$, $M_{6'\text{-}6}$, $M_{6\text{-}7}$, and $M_{7\text{-}7'}$ only. When these equations are solved:

$$\left.\begin{aligned} M_{7'\text{-}6'} &= -434.55 \text{ in-lb.} \\ M_{6'\text{-}6} &= +95.15 \text{ in-lb.} \\ M_{6\text{-}7} &= +125.99 \text{ in-lb.} \\ M_{7\text{-}7'} &= -403.71 \text{ in-lb.} \end{aligned}\right\} \quad \ldots\ldots (111)$$

The four remaining bending moments are the reciprocals of these, respectively.

Batho's Method.—This is a very elegant method, depending on two well-known properties of a beam subjected to bending. By referring to page 31, the relationship between the "elastic weight" idea and the following will be evident: Let $A\,B$ be a beam (Fig. 81), subjected to bending. As before, Equation (76),

$$d\,\phi = \frac{M_x \cdot d_x}{E\,I}$$

while the contribution to the deflection from B is,

$$x \cdot d\,\phi = \frac{M_x \cdot x\,d\,x}{E\,I}$$

Integrating over the whole length, the total change in slope, that is, the angle between $A\,B$ and the tangent at B', is:

$$\phi = \int_0^l \frac{M_x \cdot d\,x}{E\,I} = \frac{1}{E\,I} \times (\text{Area of bending moment diagram}) \ldots (112)$$

while the total deflection is:

$$\Delta = \int_0^l \frac{M_x \cdot x\,d\,x}{E\,I}$$

$$= \frac{1}{E\,I} \times (\text{Moment of bending moment area about } B)$$

$$= \frac{1}{E\,I} \times (\text{Area of bending moment} \times \text{distance of its center of gravity from } B) \quad \ldots\ldots (113)$$

Consider a complete rectangular frame, Fig. 82. Imagine the top member, $A\,B$, to be broken at its mid-point, O, and let a bending moment, M, a horizontal thrust, H, and a vertical shear, V, act on the end, O, of $A\,O$, while the reverse of these act on the end, O, of $B\,O$.

Now, consider the effect of the M, H and V, on End O of $A\,O$ separately.

The bending moment diagram for the M is as shown in Fig. 83. Imagine the frame to be resting on two hinges at D and C. The bending moment is constant over the portion, O-A-D, but between D and C, it varies uniformly from $+M$ to zero, while no bending occurs in $C\,B$ or $B\,O$. Now, determine the amount of movement, x, to the left that the point, O, undergoes. The bending moment area over $A\,O$ contributes a quantity of the second order of smallness. From Fig. 81, it is clear that a small displacement occurs perpendicularly to the member, while the movement in the direction of the

member is negligible. Now, the bending moment along $A\ D$ causes A to deflect to the left from its initial position by an amount equal to (see Equation (113)):

$$\frac{1}{E\ I_2} \times M\ h \times \frac{h}{2} = \frac{M\ h^2}{2\ E\ I_2}$$

but in doing so, it carries $A\ O$, and, therefore, the point, O, to the left by this amount.

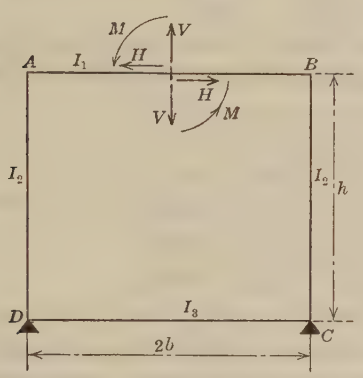

FIG. 82.

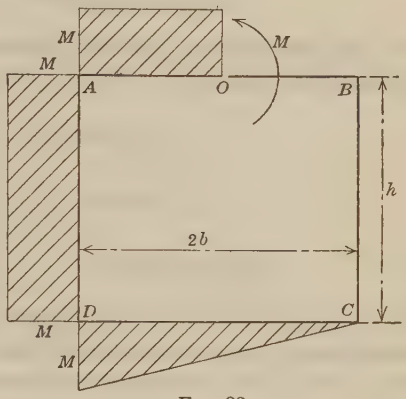

FIG. 83.

The bending moments along $D\ C$ cause a change in slope between the end tangents at D and C equal to (see Equation (112)):

$$\frac{1}{E\ I_3} \times \frac{1}{2}\ M\ .\ 2\ b = \frac{M\ b}{E\ I_3}$$

but as the angle between the tangents to $D\ A$ and $D\ C$ is constant, $D\ A$ is deflected to the left by an amount equal to $\frac{M\ b}{E\ I_3}$. In doing so, A, and, therefore, O, is moved to the left by an amount equal to:

$$\frac{M\ b}{E\ I_3} \times h = \frac{M\ b\ h}{E\ I_3}$$

The total contribution of M to the horizontal movement of O, to the left is, therefore,

$$\frac{M\ h^2}{2\ E\ I_2} + \frac{M\ b\ h}{E\ I_3}$$

It is possible to find similar expressions for the upward (y) displacement of O from its initial position, and for the total rotation between the end tangent at O of $A\ O$ and the initial position, $A\ O$ (counterclockwise). These expressions are:

$$\left.\begin{aligned} x\ \text{(left)} &= \frac{M\ h^2}{2\ E\ I_2} + \frac{M\ b\ h}{E\ I_3} \\ y\ \text{(upward)} &= \frac{M\ b^2}{2\ E\ I_1} + \frac{M\ h\ b}{E\ I_2} + \frac{M\ b^2}{E\ I_3} \\ \alpha\ \text{(counterclockwise)} &= \frac{M\ b}{E\ I_1} + \frac{M\ h}{E\ I_2} + \frac{M\ b}{E\ I_3} \end{aligned}\right\} \quad \ldots\ldots\ldots (114)$$

Similarly, the bending moment diagram for H is as shown in Fig. 84, while the contributions to x (left), y (upward), and α (counterclockwise) are:

$$\left.\begin{aligned} x \text{ (left)} &= \frac{H h^3}{3 E I_2} + \frac{H h^2 b}{E I_3} \\ y \text{ (upward)} &= \frac{H h^2 b}{2 E I_2} + \frac{H h b^2}{E I_3} \\ \alpha \text{ (counterclockwise)} &= \frac{H h^2}{2 E I_2} + \frac{H h b}{E I_3} \end{aligned}\right\} \quad \ldots\ldots\ldots\ldots (115)$$

Finally, the bending moment diagram for the V is as shown in Fig. 85, while the contributions to x (left), y (upward), and α (counterclockwise) are:

$$\left.\begin{aligned} x \text{ (left)} &= \frac{V b h^2}{2 E I_2} + \frac{V b^2 h}{2 E I_3} \\ y \text{ (upward)} &= \frac{V b^3}{3 E I_1} + \frac{V b^2 h}{E I_2} + \frac{V b^3}{2 E I_3} \\ \alpha \text{ (counterclockwise)} &= \frac{V b^2}{2 E I_1} + \frac{V b h}{E I_2} + \frac{V b^2}{2 E I_3} \end{aligned}\right\} \quad \ldots\ldots\ldots (116)$$

(The bending moment diagram for the V must be noted. To the x (left), y (upward), and α (counterclockwise) contributions of the M, H, and V, on AO, already noted, the x (right), y (downward), and α (clockwise) contributions

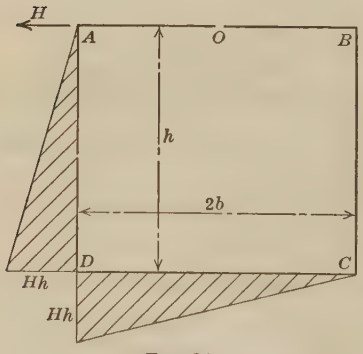

Fig. 84.

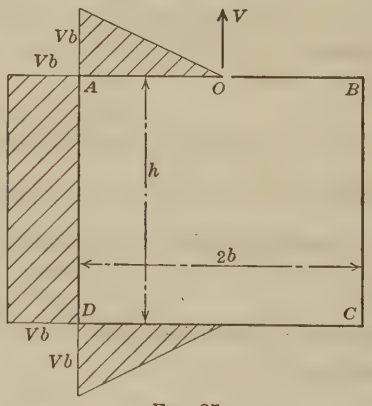

Fig. 85.

of the M, H, and V, on BO must be added. As the two V's act in opposite directions, the bending moment at the center point of DC due to the V's will be zero, and the portion shown on DC of Fig. 85 may be regarded as that due to the V on AO.) Consider now the combined effects of the two sets of M, H, and V. Notice that the M on AO, together with the M on BO, doubles the x-distance between the ends at O, and also doubles the α-angle between the end tangents at O, the respective ends being moved an equal vertical amount; in other words, the relative vertical displacement is zero. Similarly, the two H's double the x-contribution, and also the α-contribution, but the y-contribution becomes zero.

On the other hand, the two V's give zero contributions to the x and the α, but double the y-contribution. The combination of these is indicated as follows:

	x	y	α
M	2	0	2
H	2	0	2
V	0	2	0

Hence, if the top member is cut, the ends become separated under the two sets of M, H, and V, so that:

$$\left.\begin{aligned} x &= \frac{M h^2}{E I_2} + \frac{2 M b h}{E I_3} + \frac{2 H h^3}{3 E I_2} + \frac{2 H h^2 b}{E I_3} \\ y &= \frac{2 V b^3}{3 E I_1} + \frac{2 V b^2 h}{E I_2} + \frac{V b^3}{E I_3} \\ \alpha &= \frac{2 M b}{E I_1} + \frac{2 M h}{E I_2} + \frac{2 M b}{E I_3} + \frac{H h^2}{E I_2} + \frac{2 H h b}{E I_3} \end{aligned}\right\} \quad \ldots\ldots\ldots (117)$$

The x is the amount by which the O's of $A\ O$ and $B\ O$ are separated horizontally, the O of $A\ O$ lying to the left and the O of $B\ O$ to the right. The y is the vertical gap, the O of $A\ O$ lying above the O of $B\ O$. The α is the angle between the end tangents, the $A\ O$ being turned counterclockwise and the $B\ O$, clockwise.

Next, determine the effect on the two ends of the cut frame under the actual load, instead of the M, H, and V. The x must now be the horizontal distance between the ends, but with this difference that $A\ O$ and $B\ O$ overlap. The y must be the vertical distance between the ends, but the $B\ O$ must now lie above $A\ O$. The α must be the angle between the end tangents, but the $A\ O$ is now considered as being turned clockwise while the $B\ O$ is turned counterclockwise.

Equating the corresponding x's, y's, and α's, of the M-H-V-set and the load-set, gives three linear equations for the three unknowns M, H, and V. The values of M, H, and V are then those that actually exist at the center of the top member of the uncut frame.

Before applying the theory to the cross-frame, Members 6-6′-7′-7, the formulas for the deflection angles at the ends of a simply supported beam, when it is subjected to a single concentrated load, will be reproduced.

The deflection angles, α_1 and α_2*, of the beam shown in Fig. 86 are given by:

$$\left.\begin{aligned} \alpha_1 &= \frac{P}{12 E I b} (p^3 - 6 p^2 b + 8 p b^2) \\ \alpha_2 &= \frac{P}{12 E I b} (4 p b^2 - p^3) \end{aligned}\right\} \quad \ldots\ldots\ldots\ldots (118)$$

* Church's "Mechanics", Article (234), Equation (7).

Turning now to the problem of the cross-frame, 6-6′-7′-7, shown again in Fig. 88, the α, x, and y-terms from the kip load are:

$$\alpha = \alpha_1 + \alpha_2 = \frac{P}{12\, I_3\, b}\,(12\, p\, b^2 - 6\, p^2\, b)$$

$$= \frac{1\,000}{12 \times 27\,020 \times 102}\,(12 \times 60 \times 102^2 - 6 \times 60^2 \times 102)$$

$$x = \alpha_1\, h + \alpha_2\, h = \frac{P}{121_3\, b}\,(12\, p\, b^2 - 6\, p^2\, b)\, h$$

$$= \frac{1\,000}{12 \times 27\,020 \times 102}\,(12 \times 60 \times 102^2 - 6 \times 60^2 \times 102) \times 354$$

and,

$$y = \alpha_1\, b - \alpha_2\, b = \frac{P}{121_3}\,(2\, p^3 - 6\, p^2\, b + 4\, p\, b^2)$$

$$= \frac{1\,000}{12 \times 27\,020}\,(2 \times 60^3 - 6 \times 60^2 \times 102 + 4 \times 60 \times 102^2).$$

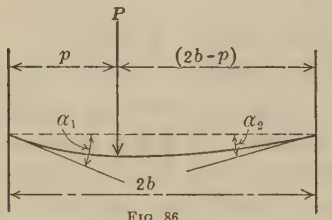

FIG. 86

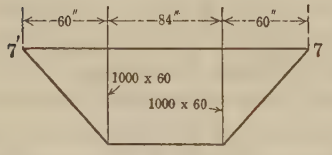

FIG. 87.

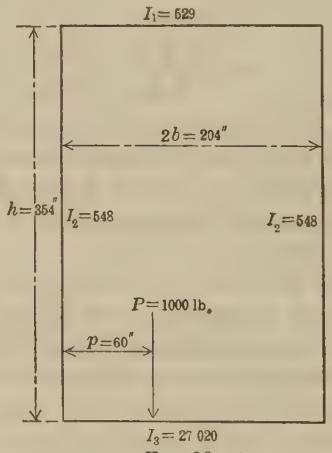

FIG. 88.

These reduce to:

$$\alpha = \frac{36 \times 12 \times 1\,000}{2\,702}$$

$$x = \frac{354 \times 36 \times 12 \times 1\,000}{2\,702}$$

and,

$$y = \frac{6\,048 \times 1\,000}{2\,702}$$

Making use of Equations (117):

$$\frac{M \times 354^2}{548} + \frac{2\, M \times 102 \times 354}{27\,020} + \frac{2\, H \times 354^3}{3 \times 548}$$

$$+ \frac{2\, H \times 354^2 \times 102}{27\,020} = \frac{354 \times 36 \times 12 \times 1\,000}{2\,702}$$

$$\frac{2\, V \times 102^2 \times 354}{548} + \frac{2\, V \times 102^3}{3 \times 529} + \frac{V \times 102^3}{27\,020} = \frac{6\,048 \times 1\,000}{2\,702}$$

and,

$$\frac{2\,M \times 354}{548} + \frac{2\,M \times 102}{529} + \frac{2\,M \times 102}{27\,020} + \frac{H \times 354^2}{548} + \frac{2\,H \times 354 \times 102}{27\,020} = \frac{36 \times 12 \times 1\,000}{2\,702}$$

giving,

$$V = +0.151 \text{ lb.}$$
$$H = +1.497 \text{ lb.}$$

and,

$$M = -110.579 \text{ in-lb.}$$

The bending moment diagram is, therefore, as shown in Fig. 89. Note how closely the values found by the two methods correspond.

	Mohr.	Batho.	Sense.
$M_{7'\text{-}6'}$	434.55	437.32	Counterclockwise
$M_{6'\text{-}6}$	95.15	92.45	Clockwise
$M_{6\text{-}7}$	125.99	128.71	Clockwise
$M_{7\text{-}7'}$	403.71	401.06	Counterclockwise

Thus far, the problem has been for an unsymmetrical load. The method will be useful in any subsequent work, where wind loads, causing an unsymmetrical load on the rails, are considered.

The present investigation, however, aims at symmetrical loads, that is, at the effect of a kip load on each rail, in the plane of the frame. Turning to Mohr's method, the bending moment area, Fig. 87, of the loads now becomes:

$$(60 \times 1\,000 \times 60) + (84 + 1\,000 \times 60) = 144 \times 60 \times 1\,000$$

$$\phi_w = \frac{144 \times 60 \times 1\,000}{27\,020} = +319.76$$

and acts at the center of the floor-beam, from symmetry.

Taking moments about the three axes used previously:

$$+ (0.3268\ M_{7'\text{-}6'} \times 163.48) + (0.3268\ M_{7\text{-}7'} \times 163.48) + 319.76 \times 280.11 = 0$$
$$+ (0.5158\ M_{6'\text{-}6} \times 163.48) + (0.5158\ M_{6\text{-}7} \times 163.48) - 319.76 \times 116.63 = 0$$
$$+ (0.5158\ M_{6'\text{-}6} \times 76.58) - (0.5158\ M_{6\text{-}7} \times 76.58) + (0.3268\ M_{7'\text{-}6'} \times 101.21) - (0.3268\ M_{7\text{-}7'} \times 101.21) = 0$$

and, as before:

$$M_{7\text{-}7'} - M_{7'\text{-}6'} + M_{6'\text{-}6} - M_{6\text{-}7} = 0$$

The last two equations give:

$$33.075\ (M_{7'\text{-}6'} - M_{7\text{-}7'}) + 39.4999\ (M_{6'\text{-}6} - M_{6\text{-}7}) = 0$$

and,

$$(M_{7'\text{-}6'} - M_{7\text{-}7'}) - (M_{6'\text{-}6} - M_{6\text{-}7}) = 0$$

hence,

$$M_{7'\text{-}6'} = M_{7\text{-}7'} \text{ and } M_{6'\text{-}6} = M_{6\text{-}7}$$

which is to be expected from symmetry.

Hence,

$$M_{7'\text{-}6'} = -838.25 \text{ in-lb.}$$

and,

$$M_{6'\text{-}6} = +221.14 \text{ in-lb.}$$

(Note that the effect of a kip load on the rail near Joint (7) is just the reverse of that of a kip load on the rail near Joint (7′). The two values just found could easily have been reached by compounding $M_{7'\text{-}6'}$ and $M_{7\text{-}7'}$ of the unsymmetrical case, giving,

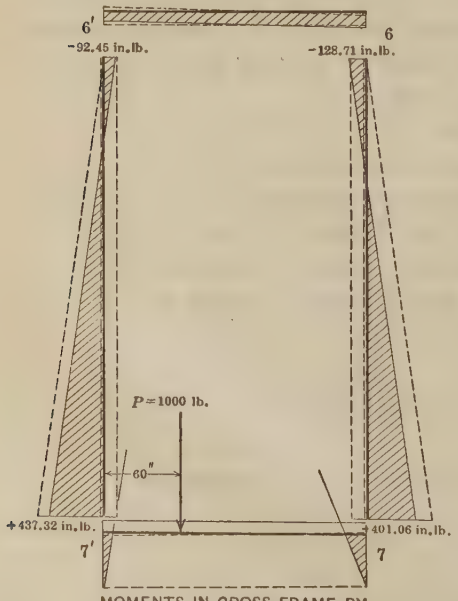
$$M_{7'\text{-}6'} = M_{7\text{-}7'} = -838.25 \text{ in-lb.}$$

and, similarly, $M_{6'\text{-}6}$ and $M_{6\text{-}7'}$, giving,

$$M_{6'\,6} = M_{6\,7} = +221.14 \text{ in-lb.}$$

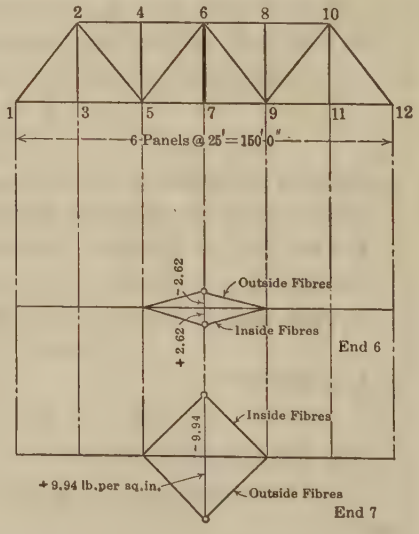
when the joint effect of the two kips is considered.)

Dr. Batho's method has the advantage over Mohr's method in that, when the x, y, and α-expressions for M, H, and V, are once established, they can be used for any frame whatever, making any new solution comparatively short. Great accuracy, however, is not certain in dealing with the differences of very large quantities. Again, the drawing of the bending moment diagram, which is a combination of four diagrams, is a source of error. Although Mohr's method is longer, its accuracy depends only on the labor expended, while the certainty of arriving at the correct signs of the bending moments is a large factor in its favor.



MOMENTS IN CROSS-FRAME BY BATHO'S METHOD.

FIG. 89.



INFLUENCE LINES OF SECONDARY STRESSES INDUCED IN 6-7 AS PART OF CROSS-FRAME.

FIG. 90.

In drawing the influence line for the vertical post, 6-7, as part of the cross-frame, note that it is zero over the whole span, except the two adjacent panels. As the member is such that all the extreme fibers are 6.5 in. away from the neutral plane, the influence lines could best be drawn for secondary stresses, and not for bending moments.

The outside fibers at End (7) of Member 6-7 are in tension, while the outside fibers at End (6) are in compression. The factor by which the bending moments are to be multiplied is $\frac{C}{I} = \frac{6.5}{548}$, giving the quantities found in Fig. 90.

5.—Application of the Influence Lines to the Solution of the Bridge Under Actual Loads

The total dead load of the bridge is 360 000 lb., or 30 000 lb. per panel point. It is assumed that the live load is a train of Cooper's *E*-50 class. Further, the impact allowance for primary stresses will be $\frac{300}{300 + L}$ of the live load contribution, in which L is the length of the span that is loaded. All the secondary stresses that arise from the live load are to be increased by 50% to allow for impact and vibration. Two typical cases will be computed.

Member 6-7.—The influence lines (Figs. 66 and 90), together with Cooper's loading diagram give the stresses. The dead load effects are the following:

The primary stress $= +41.07 \times 30 = +1\,232.10$ lb. per sq. in.

The secondary stresses, due to the rigidity of the truss joints, are zero.

The secondary stresses, due to the rigidity of the cross-frame, give:

For End (6), outside fibers.... $-2.62 \times 30 = -78.60$ lb. per sq. in.
For End (6), inside fibers.... $+2.62 \times 30 = +78.60$ " " " "
For End (7), outside fibers.... $+9.94 \times 30 = +298.20$ " " " "
For End (7), inside fibers.... $-9.94 \times 30 = -298.20$ " " " "

The maximum primary stress due to live load occurs when Wheel (5) is opposite Panel Point (7). Then,

$$\text{Primary stress} = +(12.5 \times 4.928) + 25\,(16.428 + 24.642 + 32.856 + 41.070) + 16.25\,(26.285 + 18.071 + 8.214) = +3\,790.76 \text{ lb. per sq. in.}$$

$$\text{Impact} = +3\,790.76 \times \left(\frac{300}{300 + 50}\right) = +3\,249.22 \text{ lb. per sq. in.}$$

The secondary stresses, due to rigidity of truss joints, are:

For End (6), right fibers.... $-1.5\,(147.22) = -220.83$ lb. per sq. in.
For End (6), left fibers.... $+220.83$ " " " "
For End (7), right fibers.... $+221.22$ " " " "
For End (7), left fibers.... -221.22 " " " "

The secondary stresses, due to rigidity of cross-frame, are:

For End (6), outside fibers.... $-1.5\,(243.14) = -364.71$ lb. per sq. in.
For End (6), inside fibers.... $+364.71$ " " " "
For End (7), outside fibers.... $+1\,383.67$ " " " "
For End (7), inside fibers.... $-1\,383.67$ " " " "

Hence, under the severest conditions for dead and live load combined, the total stresses at the eight end corner fibers, (Fig. 91) become:

$$f_{6a} = +(1\,232 + 3\,791 + 3\,249) + (-78.60 - 220.83 - 364.71)$$
$$= +7\,608 \text{ lb. per sq. in.}$$

and, similarly,

$$f_{6b} = +\ 8\,050 \text{ lb. per sq in.}$$
$$f_{6c} = +\ 8\,936 \text{ " " " "}$$
$$f_{6d} = +\ 8\,494 \text{ " " " "}$$
$$f_{7a} = +10\,175 \text{ " " " "}$$
$$f_{7b} = +\ 9\,733 \text{ " " " "}$$
$$f_{7c} = +\ 6\,369 \text{ " " " "}$$
$$f_{7d} = +\ 6\,811 \text{ " " " "}$$

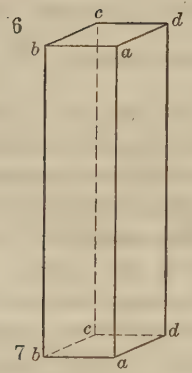


FIG. 91.

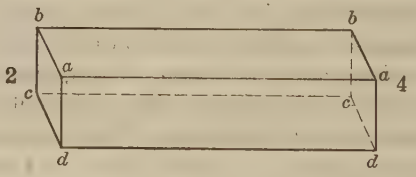

FIG. 92.

Member 2-4.—Referring to the influence lines (Figs. 59 and 71), the dead load gives:

Primary stress = — 2 233.20 lb. per sq. in.

The secondary stresses, due to rigidity of truss joints, give:

For End (2), top fibers..... + 102.00 lb. per sq. in.
For End (2), bottom fibers..... — 104.40 " " " "
For End (4), top fibers..... — 297.00 " " " "
For End (4), bottom fibers..... + 303.30 " " " "

The secondary stresses, due to the rigidity of the top lateral system, give:

For End (2), a bending moment area = + 49 049.25
For End (4), a bending moment area = — 66 307.05

These are to be multiplied by $\pm \frac{10.5}{2\,852.45}$ and $\pm \frac{12}{2\,852.45}$, giving,

For End (2), cover-plate outside fiber..... — 270.83 lb. per sq. in.
For End (2), cover-plate inside fiber..... + 270.83 " " " "
For End (2), bottom angles outside fiber..... — 308.02 " " " "
For End (2), bottom angles inside fiber..... + 308.02 " " " "

and,

For End (4), cover-plate outside fiber..... — 366.12 lb. per sq. in.
For End (4), cover-plate inside fiber..... + 366.12 " " " "
For End (4), bottom angle outside fiber.... — 418.42 " " " "
For End (4), bottom angle inside fiber.... + 418.42 " " " "

The maximum primary stress due to live load occurs when the bridge is almost fully loaded, namely, when Wheel (9) is at Panel Point (5). Then:

Primary stress = — 5 729.41 lb. per sq. in.,
Impact = — 3 819.61 " " " ".

The secondary stresses, due to the rigidity of the truss joints, become:

For End (2), bottom fibers.... — 1.5 (209.57) = — 314.35 lb. per sq. in.
For End (2), top fibers..... + 307.43 " " " "
For End (4), bottom fibers.... + 1 038.95 " " " "
For End (4), top fibers..... — 1 016.09 " " " "

The secondary stresses, due to the rigidity of the top lateral system, become:

For End (2), cover-plate outside fiber..... — 693.39 lb. per sq. in.
For End (2), cover-plate inside fiber..... + 693.39 " " " "
For End (2), bottom angle outside fiber..... — 792.44 " " " "
For End (2), bottom angle inside fiber..... + 792.44 " " " "
For End (4), cover-plate outside fiber..... — 943.89 " " " "
For End (4), cover-plate inside fiber..... + 943.89 " " " "
For End (4), bottom angle outside fiber..... — 1 078.74 " " " "
For End (4), bottom angle inside fiber..... + 1 078.74 " " " "

Hence, under the severest conditions, the total stresses at the eight corner fibers, Fig. (92), become:

$$f_{2a} = -(2\,233.20 + 5\,729.41 + 3\,819.61) + (102.00 - 270.83 + 307.43 - 693.39)$$
$$= -12\,337 \text{ lb. per sq. in.}$$
$$f_{2b} = -10\,409 \text{ " " " "}$$
$$f_{2c} = -11\,101 \text{ " " " "}$$
$$f_{2d} = -13\,301 \text{ " " " "}$$
$$f_{4a} = -14\,406 \text{ " " " "}$$
$$f_{4b} = -11\,785 \text{ " " " "}$$
$$f_{4c} = -8\,943 \text{ " " " "}$$
$$f_{4d} = -11\,937 \text{ " " " "}$$

6.—Conclusion

By means of the set of influence lines for the primary and secondary stresses in the truss members, due to the rigidity of the joints in the plane of the truss, and the sets of influence lines for the top lateral system and the cross-frames, it has been possible to determine the maximum stresses that occur at the end corners of all the members except the bottom chords. In order to obtain the maximum stresses in the bottom chords, it is first necessary to obtain the influence lines for the floor system. With such a complete set available, superimpose the secondary stresses due to dead load together with those brought

into play by the axial loads. At this point it would be well to use Westergaard's analysis (35). It must be remembered that the variation between two end moments in a certain plane follows the straight-line law, consequently, it is possible to obtain influence lines for secondary stresses due to the rigidity of the joints at any section of the member. All the influence lines that have been found thus far, are for sections at the joints. As end connections prevent the determination of end effects, and, also, as these connections result in stresses quite different from what they would be if members were supposed to be rigidly held at the very ends, observations are taken beyond the gusset-plates, etc. It is possible, however, to make an analysis for the secondary stresses at some such section and then verify them experimentally. Discrepancies are to be expected, but just as tension specimens have under the clamps a distribution of stress which is not uniform, and to all intents and purposes a uniform distribution a little beyond the clamps, so it may be inferred that, in practice, the theoretical stresses at the corner fibers of a member of a bridge will exist at sections beyond the end connections.

So much for the dead and the live load; consider the wind load separately. Its presence means certain horizontal loads at the panel points. An analysis of the top and bottom lateral systems will indicate the extra primary stresses in the chords, together with the additional secondary stresses in the two horizontal planes. The primary stresses induced by the wind in the top and bottom chords of each truss cause additional secondary stresses in these trusses. A set of influence lines for these must be drawn. Again, the overturning effect of the wind on the train throws more weight on the leeward rail than on the windward. Not only will the cross-frame secondary stresses due to the live load be effected, but, also, the secondary stresses in the two trusses caused by the live load. Imagine that the wind causes the load of 1 kip on the leeward rail to become 1.05 kips and that on the windward, 0.95 kip. With little effort the cross-frame secondary stresses may be determined from the analysis given on pages 127 to 143, while the secondary stress quantities found on pages 108 to 118 are to be multiplied by 1.05 to obtain those in the leeward truss and by 0.95 to obtain those in the windward truss. Finally, the top lateral system needs revision.

Traction effects should now be considered in more or less the same way. When all the influence lines have been determined, they should be combined in such a manner as to arrive at the maximum corner stress that a member can possibly have. It will generally be found to occur when the primary stress is a maximum. It seems justifiable, therefore, to compound the secondary stresses arising from axial and transverse loads at that moment with those already found from the end moments, and thus obtain a fairly good estimate of what happens along the length of the member.

The analysis given on pages 143 to 145, clearly shows how widely the four corner stresses at the end of a member may differ. Any device that lessens this difference is to be encouraged. In practice, the top members of the cross-frames are often longer than their theoretical length by an amount that introduces secondary stresses opposite in effect to those given on pages 127 to 143,

and equal to the dead load plus one-half the live load contribution. In large structures, too, either the top chords are intentionally made longer or the bottom chords shorter than their theoretical unstressed lengths, so that when the dead load acts, the top chords become straight; the axial effect, which is intensified with bent chords, is, therefore, minimized.

In conclusion, the writer believes that he has demonstrated conclusively, which methods the practical engineer must adopt in order best to obtain proper results. His idea of compounding secondary stresses as indicated is probably far from the truth, but it is an endeavor to explain, by means of the present limited knowledge of mathematics and mechanics, the true state of affairs in a bridge. He has indicated how this study can be pursued to a conclusion and, although he frankly acknowledges that it may never be adopted in its complete form in practice, he sincerely hopes that all engineers will regard such a study not so much as a possible means of material benefit but as a search for truth.

Acknowledgments

The writer wishes to express his thanks to H. M. MacKay, M. Am. Soc. C. E., and Dr. Cyril Batho, of McGill University, and to Henry S. Jacoby, M. Am. Soc. C. E., and Dr. E. W. Rettger, of Cornell University, for their instruction, advice, and encouragement.

DISCUSSION

O. H. AMMANN,* M. AM. SOC. C. E. (by letter).—The author deserves credit for his painstaking and elaborate investigation. For practical purposes the outstanding merit of this paper lies in its critical comparison of various methods of calculating secondary stresses.

Contrary to Mr. von Abo the writer does not expect that engineers will avail themselves extensively of a systematic determination of secondary stresses in bridges, nor does he believe that, in general, such practice would produce bridges of greater strength and economy than those built with what the author calls "the factor of ignorance".

An experienced engineer, of course, must be familiar with the character of secondary stresses, but he will not trouble himself with their determination in each ordinary case. For an unusual structure he will generally know where large secondary stresses are to be expected and confine himself to such critical determinations. Nor will it be a question of extreme refinement for he knows that many "practical factors" affect the true values and that even the true secondary stresses are not at all a criterion or measure for the safety or ultimate carrying capacity of a bridge. He will prefer therefore such methods as will determine these stresses, where desirable, in as simple a manner as is compatible with a fair degree of accuracy.

The writer has calculated the secondary stresses in a number of trusses and has invariably used the semi-graphical method of Mohr with which he was most familiar and which appeared to him to have the advantages of simplicity and lucidity.

A modification of this method which appears to possess its advantages to an even greater degree has since been developed by M. Ros and is contained in a report by the Technical Commission of the Swiss Association of Structural Steel Manufacturers on a comprehensive investigation of secondary stresses. A brief résumé of that report is given in a recent article by the writer.†

The author mentions only casually the effect of gusset-plates on the true secondary stresses, yet this is most important and, more than anything else, suggests the futility of extreme accuracy in the theoretical determination of secondary stresses for the purpose of design. He assumes that the theoretical secondary stresses exist as sections beyond the end connections. Although that arbitrary assumption is often made, and is, perhaps, as good as any other in many practical cases, it is far from correct where gussets are rigid and comparatively large. The true state is extremely difficult or almost impracticable of determination by theory, but from practical observations, especially those previously mentioned, it appears that the maximum stresses beyond the end connections may be found approximately by multiplying the secondary moments at the theoretical ends of a member by the ratio of the theoretical to the actual length of the member (between connections) and assuming these increased moments to be applied at the points of connection with the gussets.

* Bridge Engr., Port of New York Authority, New York, N. Y.

† *Engineering News-Record*, October 23, 1924.

It is evident that in many cases this correction means considerably greater secondary stresses. It remains an open question, however, as to whether rigid gussets, producing large secondary stresses, are not a source of strength rather than of weakness. The writer is inclined to the view that the former is the case, although he feels that this question offers a field for further investigation.

William Cain,* M. Am. Soc. C. E. (by letter).—This valuable paper on secondary stresses in bridges is unique, in that it gives, not only the theory of various methods pertaining to secondary stresses, but likewise their application to a railway bridge, with the numerical or graphical work required for complete solutions, the main object being a critical comparison of the methods with a view to selecting the best of them, considering the labor involved and the accuracy. This task the author has accomplished successfully, and the full numerical solutions show the comparative merits, from a practical point of view, of the several methods. The author finally concludes that, for the railroad truss, Manderla's method is to be preferred; the writer is inclined to agree with him, perhaps using as a check the Mohr semi-graphical method. The computations by either of these methods involve only three decimal figures, whereas Müller-Breslau's or Mohr's elastic weight methods introduce a much greater number of equations, which thus require many more decimal places for an accurate solution.

The writer having used the Gauss method of elimination considerably, warmly commends it. By this method, each derived equation is checked at once, so that the computer has the great satisfaction of being assured of correct results at every stage of the elimination. Professor Turneaure† has given a complete derivation of the required formulas by Manderla's method, together with a systematic method of procedure for their solution, which is to be commended. Tentative methods, such as those of Ritter and Mao, are not very attractive when direct solutions that require no more labor are available.

‡In connection with the development of Mohr's elastic weight method, the author states that, after the axes are turned 90°, "$u_{4\psi}$ of Equations (69) may be regarded as the negative of the sum of the moments of the ψ's about the new u'-axis, while $v_{4\phi}$ is the sum of the moments of the ϕ's about the new v'-axis." Evidently, if the ψ's are turned to a vertical position, they can have no moments about a horizontal line (the new u'-axis); and, if the ϕ's are turned to a horizontal position, they can have no moments about a vertical line (the new v'-axis). (See Fig. 93.)

From Equations (68):

$$u_{4\psi} = (u_4 - u_1)\,\psi_1 + (u_4 - u_2)\,\psi_2 + \dots,$$
$$v_{4\phi} = -[(v_4 - v_1)\,\phi_1 + (v_4 - v_2)\,\phi_2 + \dots]$$

The distances $(u_4 - u_1), \dots, (v_4 - v_1), \dots$ (Fig. 93), are unchanged by the rotation of the axes; but if the ϕ's are regarded as forces acting horizontally

* Prof. Emeritus, Univ. of North Carolina, Chapel Hill, N. C.

† Johnson, Bryan and Turneaure, "Modern Framed Structures," Vol. II.

‡ For a discussion of this point, see p. 208 of the author's closing discussion.

and the ψ's as forces acting vertically, then taking counterclockwise moments as positive:

$$du_4 = (u_{4\psi} - v_{4\phi})$$
$$= \Sigma \text{ moments of } \psi\text{'s about the new } v'\text{-axis}$$
$$+ \Sigma \text{ moments of } \phi\text{'s about the new } u'\text{-axis}$$

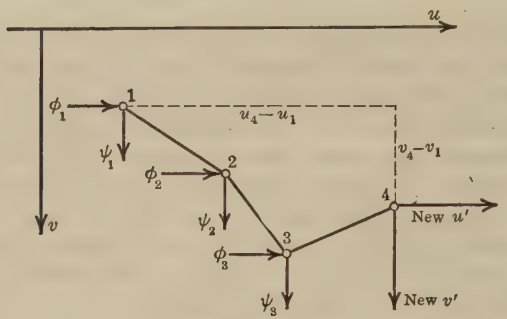

FIG. 93.

Further, the author shows, when $du_4 = 0$, that the origin of the new axes can be taken anywhere, as illustrated in the triangles of Fig. 55, where u_2, v_2, correspond to the new u'-axis and the new v'-axis, respectively. Formulas such as II 2 in Table 18 are at once derived by the formula just stated. The author will doubtless clear up the ambiguity mentioned. He is requested to explain (1) why the co-ordinates, u_1, v_1, etc., are not drawn parallel to the axes, u, v, respectively, as is usual, and (2) as to the signs of the co-ordinates.

This method of elastic weights is readily adapted to the rectangular frame, as the author illustrates with an example. He also gives Batho's interesting analysis, leading to Equations (117), which apply to any rectangular frame, and thus makes possible a solution by mere substitution. The author has failed to note two important papers on statically indeterminate frames, one by Mikishi Abe,* M. Am. Soc. C. E., the other by Messrs. Wilson, Richart, and Weiss.* These papers are especially valuable to the designer, in that they give readily applied formulas for numerous statically indeterminate structures.

In conclusion, the writer desires to express his appreciation of the author's notable contribution, which has evidently involved great labor and which leads to practical conclusions that will prove of material service to engineers.

ALMON H. FULLER,† M. AM. SOC. C. E. (by letter).—Although this paper may not contain much that is new in the sense of theoretical or experimental research, it is a valuable contribution to the subject of secondary stresses. The procedure of computation and the comparison of methods are of value to all structural engineers, especially to those, still in the majority, who have not given personal attention to this phase of analysis. The emphasis on the

E.; and Univ. of Illinois *Bulletin No. 108*, November 4, 1918, "Analysis of Statically Indeterminate Structures by the Slope-Deflection Method," by W. M. Wilson, F. E. Richart, Assoc. M. Am. Soc. C. E., and Camillo Weiss.

† Prof., Civ. Eng., and Head of Dept., Iowa State Coll., Ames, Iowa.

effect of lateral and sway-bracing and on the general subject of stress distribution helps greatly in producing a well rounded investigation.

The value of the paper is enhanced by references to, and brief comments on, the field measurements of stresses which were available. Other similar investigations to which the author refers as not being available may be many and, if brought to light, may be co-ordinated so as to be of considerable value. To this end, the writer contributes his mite by giving some significant data which are yet only published in part.

The results for 1922* and for 1923† of a four-year program in stress measurements on bridges have appeared since the paper was written. While the object has been primarily to investigate impact in highway bridges, the study of stress distribution under static and dynamic loads has naturally followed, and although the greater part of the work relates to floor systems, considerable data on truss members have been obtained. For instance, the 1923 results for the hip vertical of the Skunk River Bridge show a unit stress of 6 200 lb. per sq. in. on the inside flanges (the ones to which the floor-beams are attached) and 2 400 lb. on the outside flanges, under an impact of about 25% (live load stresses with the load in motion on a smooth floor exceed by 25% the static stresses for the same load). Under high impact (above 100%), the respective values are 13 000 and 4 800 lb. per sq. in. Corresponding stresses for the hip vertical of the Rowland Bridge are 4 100, 1 700, 8 500, and 5 000 lb. per sq. in. A tendency will be noted in the Rowland Bridge for a smaller proportionate range of stress under the more severe loading. The bending in these members is almost entirely in planes perpendicular to the trusses; there is little indication of secondary stresses due to bending in the planes of the trusses.

The results of some of the writer's strain-gauge readings for secondary stresses on the Niagara Arch‡ have already been published. They indicate the bending in horizontal and in vertical planes and are averages of two or more readings. The individual readings, not given in that paper, indicate even a greater range of stress; they show that for the upper panel point, U_2, for a given static live load, G_2, the range of the stress in the upper chord to the left is from 5 300 lb. per sq. in. compression to 2 800 lb. tension; in the upper chord to the right, from 100 to 4 800 lb. compression; in the vertical, 1 000 to 5 200 lb. compression; and in the diagonal, from 2 800 to 7 000 lb. tension. For the corresponding members at the point, U_6, for a given static live load, D_1, the values are, respectively, 3 000 lb. per sq. in. compression to 800 lb. tension, 1 400 to 3 600 lb. compression, 400 lb. tension to 6 200 lb. compression and 2 400 to 4 200 lb. tension.

The results of strain-gauge readings at sixteen points on each of three sections of four columns during the course of erection of an eighteen-story building, have been published§ by the writer. In general, the distribution of

stress was excellent. There was one exception, however, of sufficient range to merit attention, although not to cause alarm. Just above the base of one column under a load of about 700 000 lb., the average stress was about 10 000 lb. per sq. in. and the range from less than 7 000 to more than 14 000 lb. The average of the four lowest points on one side of the column was 7 400 lb. per sq. in., and the average of the four highest corresponding points on the other side of the column was 13 600 lb. This shows an unmistakable bending about an axis very nearly parallel to two sides and suggests something which should be known, and which, if anticipated, might be prevented.

As yet, none of these values has been checked against computed secondary stresses, but, regardless of what the comparison may be, they show such a range as to give encouragement for further investigations from both theoretical and experimental standpoints. It would seem fortunate if field measurements could be taken on the structure for which the author has made such satisfactory computations.

K. P. BAHJEJIAN,* JUN. AM. SOC. C. E. (by letter).—On comparing the methods of Mao and Müller-Breslau it is noted that their fundamental equations are similar in form. If Equation (80) is applied to the angle at A in Figs. 7 and 8, and the same notation is used as indicated in these diagrams, remembering that f and M have the same subscripts, there is obtained:

$$6\,E\,.\,\Delta\,\alpha = \frac{l_1}{y_1}\,(2\,f_2 - f_1) - \frac{l_2}{y_2}\,(2\,f_3 - f_4)$$

The first form of Equation (43) is:

$$6\,E\,.\,\Delta\,\alpha = (2\,\rho_3 - \rho_4) - (2\,\rho_2 - \rho_1)$$

in which,

$$\rho_3 = \frac{M_3\,l_2}{I_2} \text{ and } M_3 = \frac{f_3\,I_2}{y_2}, \text{ whence } \rho_3 = \frac{f_3\,l_2}{y_2}$$

Similarly,

$$\rho_4 = \frac{f_4\,l_2}{y_2};\ \rho_2 = \frac{f_2\,l_1}{y_1};\text{ and } \rho_1 = \frac{f_1\,l_1}{y_1}$$

Making these substitutions, the equation becomes:

$$6\,E\,.\,\Delta\,\alpha = \frac{l_2}{y_2}\,(2\,f_3 - f_4) - \frac{l_1}{y_1}\,(2\,f_2 - f_1).$$

As bending moments in a clockwise direction in the latter method are regarded as positive, and in the former as negative, these equations are really identical.

The author has called attention to the fact that in applying the fundamental equations to a given truss, Mao "assumes two quantities known at the start, and using these throughout the process, finally arrives at two simultaneous equations the solution of which determines the two assumed quantities", just as described in connection with Fig. 9 for Müller-Breslau's procedure modified by Páez. Mao assumes the secondary stresses, f_1 and f_2, in the first member, 1-2, of the truss, instead of ρ_1 and ρ_2 for the same member.

* In Chg., Valuation Dept., East Penn Elec. Co., Pottsville, Pa.

C. A. P. Turner,* M. Am. Soc. C. E. (by letter).—The author defines secondary stress in a truss member as equal to one-half the difference between the extreme fiber stresses at any section.

Stress variation in a compression member, however, may largely result from column action of the primary stresses independent of truss distortion (the cause of so-called additional stress), but depending on the buckling or torsional tendency incident to the make-up of the built section, which is explicitly disregarded in the proposed analysis.

Secondary stress theories were first developed to explain the collapse of certain German bridges designed in accordance with the letter of commonly used formulas and customary working stresses but lacking in engineering judgment as to the make-up of the sections and the application of formulas not theoretically perfect to provide for the primary stresses in the compression member. Between the behavior of the serviceable and the unserviceable design there exists a wide difference unless the foregoing ingredient of good practice is taken into consideration. Even then the scope of assumption necessary to bridge the gap needs to be wide indeed, unconfined by the narrow limitations of Hooke's law on which elastic theory is founded.

According to the author:

"In 1877, the Technical University of Munich offered a prize for the solution of a problem, worded by Professor Asimont as follows: What stresses arise in the members of a bridge truss owing to the fact that the angles of the truss triangles suffer no change?"

In the published theory of secondary stress is found no experimental measurement proving that the angular distortion of the gusset-plates is of such a low order, in comparison with the minute angular change in the truss triangles, that it may be disregarded. Computation covering this pertinent question is likewise lacking, notwithstanding that the accuracy and utility of the analysis depend on these relative magnitudes.

Engineering opinion may be divided into two schools of thought on the question of the value of the stereotyped computation of secondary bending stresses. The old school regards such secondary stresses as an element of additional strength in the well proportioned frame—one free from radically acute angles each of the elements of which presents a small departure only from the equilateral triangle. Under such practical limitations the elastic stiffness of gusset-plates at the joints reduces the vibration under rolling load and the bending resulting from the weight of the members. In the case of compression members the restraint of the ends caused by the gusset-plates increases the column strength. In the top chords distortion of the truss triangles particularly in a camel-back simple span results in a favorable upward shifting of the center of compression from the lowered position caused by the bending due to the weight of the member. The trend of present practice in the progressive substitution of stiff riveted construction for pin-connected spans strongly supports this viewpoint.

The younger school of theorists, on the other hand, scent danger in all secondary bending stresses regardless of their direction or sign and treat

* Cons. Engr., Minneapolis, Minn.

them as an invariable source of weakness, to be combined numerically instead of algebraically with the primary stresses. Contrary to the elastic theory the strength is computed as proportional to the principal stress and independent of the greatest displacement. Now, displacement is the joint product of the principal stress and the shear that is explicitly ignored in the premise on which the theory rests.

In the ordinary built-up steel column, twisting or buckling of webs or outstanding flanges is the predominant distortion preceding the plastic bending incident to the follow-up motion of the machine after the elastic resistance has been overcome. This rotary or buckling tendency of the compression member made up of thin plates and angles is neglected in the ordinary column theory of primary stress. This deficiency in proportioning metal for the primary stress, although unrelated to truss distortion, is assumed to be provided for in the secondary stress computations advanced to explain the collapse of defective bridge designs.

The value of secondary stress theory as a useful explanation of these failures narrows down to a question of the relative magnitude of the torsional weakness of the column under primary stress (disregarded in column theory) and of the bending weakness under truss deformation. Torsional weakness varies with the form and make-up of the section, as shown by tests of angle and pipe struts of equal slenderness ratios, having pin and ball-and-socket bearings. Round pipe columns develop the same strength whether the ends are hinged on a pin or fitted with a spherical bearing. On the contrary, angle and T-sections, the slenderness ratios of which are greater than 140, develop only 57% of the strength with round ball-and-socket bearings that they develop with pin-bearings; and the pin-bearing, angle-iron strut, develops only about 85% of the resistance of the pipe strut. Nevertheless, according to the common (but defective) theory of primary stress resistance of simple compression members, these divergent types and details would be computed as possessing identically the same strength. If such a major deficiency exists in providing against the weakness of members under primary stress with divergent forms of section, the cause should be investigated before endeavoring to compute the magnitude of secondary sources of weakness.

As the strength of the entire section is the sum of the resistance of its parts plus their combined action as co-ordinated in the form or make-up of the cross-section, the column section may be divided lengthwise into narrow parallel strips. The slenderness ratio of each strip of the hollow column is less than that of the whole, and therefore the strength of the sum of the strips would be less than the whole by the amount of their combined action in supporting each other. In the round pipe the strips support each other so perfectly that pure torsion would simply increase the length of each as in the case of a solid section; but with an angle, T, or star-shaped section, twist shortens the section and a tendency develops to twist out as well as to bend out from under the load. The tendency of an outstanding flange to bend is restrained by the metal normal to its least dimension; hence, if several flanges have like tendencies to buckle as in a Z, T, or star-shaped section, rotary

distortion results, the tendency varying as the square of the projecting length of flange divided by the distance between the centers of gravity of this and the opposing part which resists the buckling.

This matter has been discussed at length elsewhere* by the writer, the conclusion being that the compressive resistance of sections such as a T-section composed of one 30-in. by ½-in. web and two 5 by 3½-in. by ⅝-in. angles, or star-shaped sections composed of one 20-in. by ⅜-in. plate, two angles, 4 by 4 in. by ⅜ in., and two plates, 10 in. by ⅜ in. (similar to the make-up of the defective German designs) is so much lower than the apparent strength computed by ordinary formulas, that their collapse under primary stresses should have caused no surprise or comment. As the collapse of the defective German designs may thus be accounted for without resorting to the theories of secondary stresses evolved by Manderla, Müller-Breslau, Mao, and Ritter, it is obvious that the bending stresses computed by these methods are greatly exaggerated or largely imaginary. For a given loading it is evident also that two unrelated causes cannot account *in toto* for the same phenomena.

The assumptions underlying the conventional secondary stress theories may be considered as follows:

(*a*) That the secondary effects of primary stress are confined to truss distortion or bending of the member in the plane of the truss without torsional strain.

(*b*) That the gusset connections at the joints may be assumed as absolutely rigid, whereas the members connected by the joint plates are treated as elastic.

(*c*) That safety from failure is measured by extreme fiber stresses independent of shear strain.

(*d*) That the moment of inertia of a member under predominant axial stress accompanied by minor transverse stress is of the same magnitude as if the member were subject to pure flexure.

(*e*) That the stress mechanism of columns and beams may be treated as similar in nature for practical purposes of computation.

Assumption (*a*) is inadmissible, for torsion of the column or its elements resulting in the buckling or the rotary distortion of an unsymmetrical section is the greatest and most dangerous of indirect stresses; Assumption (*b*) is inconsistent with Hooke's law on which elastic theory is founded; Assumption (*c*) is discredited by experiment; Assumption (*d*) is at least fourfold in error; and Assumption (*e*) would upset fundamental conceptions of the theory of internal stress and is moreover discredited by experience, which teaches that the short column cannot be logically proportioned by Euler's formula for the bending of long columns.

The kind of accuracy so laboriously attained under these assumptions recalls the case of a shop drawing once checked by the writer. The lettering and figures were as neat as copy-plate, but each different rivet space was given in odd $\frac{1}{32}$ in. or $\frac{1}{64}$ in. Pressed as to his reason for such spacing, the draftsman stated that it made the drawing look accurate. On further questioning regarding field connections that did not match and main dimensions

* "Elasticity and Strength of Materials," Section IV.

that were 1½ ft. in error, the man assured the writer he would "get a looking glass" to read his scale closer.

Looking with a similar instrument into the German assumption of identity as to stress mechanism of columns and beams in flexure, it would appear that whereas, for the beam, the deflection is closely measured by the extreme fiber stress, in the case of the column it is not; this latter is because, unlike the deflection of the beam, it is determined largely by shear distortion which is regarded as negligible in the beam. To locate the axis of the compression member about which the shear distortions are balanced, there is found the locus of the center of pressure instead of the center of gravity of the section so that the moment and the resistance to moment differ radically from beam action. Thus, in the beam, the greatest tensions and compressions are parallel to the axis and their values on a cross-section of severest intensity reduce to zero at the center of gravity of the section. In the column, on the contrary, the greatest tensions are at right angles to the axis instead of parallel or slightly inclined while the compressive stress is a minimum at one outer fiber, a maximum at the other, and a mean at the center of the section instead of zero as in the beam. Accordingly, the same conditions of bending and the same moments of inertia cannot apply to two conditions of stress so different from each other.

In tests it is observed that when the column commences to bend appreciably its equilibrium is unstable and it is practically on the point of failure. In reaching this point the state of stress within the column must have been changing radically with very little deflection. Stated in another way, the bending of the column does not take place in proportion to the applied force; nevertheless, as the writer has endeavored to show elsewhere,* if the divergent state of stress from that of the beam is given proper consideration it does follow Hooke's law.

Any effort by which the magnitude of subsidiary stresses may be rationally determined is a matter of scientific interest. It becomes of practical value only as these stresses attain substantial magnitude. Ordinarily, torsional stresses and shearing stresses in the compression member (which are neglected and ignored in the German theory of secondary stresses) greatly overshadow the longitudinal secondary stresses produced by truss distortion which, therefore, need to be given consideration only in the case of improper design.

By avoiding acute-angled triangles which cause the deformations to become excessive, the secondary bending stresses are reduced to a negligible amount. Nevertheless, their precise determination will be of scientific interest when developed in a manner consistent with Hooke's law, with the elastic bending of the compression member, and with the known characteristics of the state of stress. These have been disregarded in the theories heretofore proposed.

P. L. Pratley,† Esq. (by letter).—The writer believes that the collection and criticism of the various methods discussed by the author, by which the distortional stresses in a frame may be determined, is a really valuable work.

* "Elasticity and Strength of Materials," Section IV.

† Montreal, Que., Canada.

A paper of this nature, however, is not one that lends itself readily to discussion, as so much of it is demonstration, either of theory or methods of calculation. The author is certainly to be congratulated on the patience displayed in the prosecution of such an amount of tedious labor, and also on the general clearness with which he has presented both the methods of the various investigators and his own conclusions.

For about fifteen years the writer has been accustomed to calculate these distortional stresses for bridge trusses wherever either the magnitude, the layout, or the duty of the structure suggested, and although he claims some acquaintance with most of the methods presented, he must confess total ignorance of that attributed to Dr. Mao. From the study made in the paper he is decidedly of the opinion that this new method cannot be considered as of practical value, and agrees with the author that the solutions of Manderla and Mohr are much to be preferred. On the other hand, from his own experience, the writer would reverse the order in which the author classifies these two methods, preferring the semi-graphical method of Mohr and Williot. Having begun with Manderla, he has come to accept the other as more quickly solvable, and more "visual". To his mind the Mohr method deals with actualities, rather than with imaginary or artificial functions such as are introduced by Mao and other investigators. The ease with which the angles and moments can be plotted, makes the graphical method a realistic means of portraying to the eye the actual conditions in the framework, and making the calculator familiar with the comparative values. Furthermore, the functions used in the Mohr analysis are susceptible to experimental checking, as has been demonstrated by Swiss engineers. The writer solves Equations (55) by a simple method of successive approximation; four or five repetitions always result in sufficiently accurate results for $\Sigma M = 0$ to be established at all panel points. The author points out in his Tables 16 and 24 that the Mohr method is practically as accurate as any, giving results almost identical to ten decimal places with the elastic weight and the improved Manderla methods.

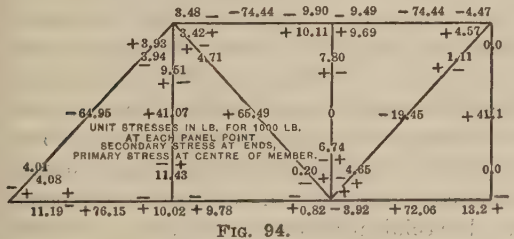

FIG. 94.

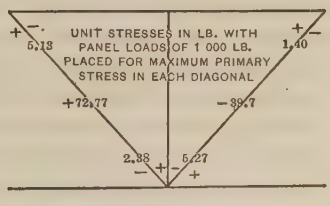

FIG. 95.

The influence line diagrams Figs. 58 to 68, inclusive, are also of value, and the thanks of the profession are due the author for compiling them. The writer has collected from these diagrams the primary and secondary stresses due to full load conditions (which is the case usually adopted for calculating purposes) and for comparison has added the corresponding diagrams for the two diagonals under the loading which produces their maximum primary stress (Figs. 94 and 95). From these it appears that the full load condition

does give satisfactorily close approximations to the maximum combinations, for even at the bottom of the first diagonal where the variation is the greatest, the fiber stress amounts only to about 270 lb. per sq. in., taking a panel load of 125 000 lb. (approximately E-50). In Fig. 96 is shown the total resultant fiber stress on gross areas, the truss being fully loaded with 125 000 lb. at each panel

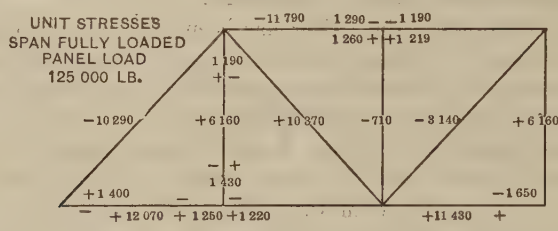

FIG. 96.

point. The secondary stress is given only where it exceeds 1 000 lb. per sq. in., and it will be seen that it never reaches 11% of the common unit, 16 000 lb.; so that for this type of truss it can be safely neglected. An initial adjustment in the length of the vertical members is sometimes resorted to, as a means of minimizing the secondary stresses induced in the chords in this type of truss.

HENRY S. JACOBY,* M. AM. SOC. C. E.—It may be of interest to the members of the Society to know some items of human interest connected with the work on secondary stresses in the Graduate School of Cornell University, which culminated in this paper. In the fall of 1912, Mr. José Páez came to the University for a year's graduate study before returning to the Philippine Islands, his native land. He had completed his secondary education in Germany, had been graduated in Civil Engineering at the Zurich, Switzerland, Polytechnicum, and had been employed in the Engineering Department of a bridgeworks in Berlin, Germany, for a year, while additional practical experience had been secured during one or more summer vacation periods. When asked whether he had considered the choice of a thesis subject he replied that he would like to write a thesis on secondary stresses. This was a delightful surprise, since this subject had been in the speaker's mind for some years, awaiting a student who had the requisite qualifications. Mr. Páez had been accustomed to use French, German, and English, in addition to his native language. In order to secure some knowledge of the relative advantages of the different methods of computing secondary stresses, he applied most of the methods described in Mr. von Abo's paper to a single bridge truss. He called special attention to the time and labor saved by the use of Gauss' theory of normal equations, thus also checking the solution step by step. He was led to use this method throughout because he had chosen Geodesy as the minor subject in his graduate work. He also developed an additional approximate method.

Mr. Thomson E. Mao, a Chinese student, came to Cornell University for a year's graduate work in 1916. His thesis was on the design of a two-hinged spandrel-braced arch with cantilever extensions on each end. He studied the

* Prof. of Bridge Eng., Emeritus, Cornell Univ., Bethlehem, Pa.

thesis of Mr. Páez and voluntarily extended his own thesis beyond its original plan by computing the secondary stresses in the arch truss for a load at each panel point separately, which required the solution of ten sets of simultaneous equations with thirty-five in each set.

Mr. Mao's interest in secondary stresses due to this experience did not diminish after leaving the University to secure practical experience with a large bridge company in Pittsburgh, Pa. He thought that there ought to be some method which would enable the necessary computations to be made with less labor. He devoted much study to the subject for several years, and finally both the analytic and graphic methods which he discovered were presented in a thesis for the degree of Doctor of Philosophy at the Carnegie Institute of Technology. Time did not permit Mr. Mao to apply his methods beyond the case of full live loading. When Mr. von Abo applied both of Mao's methods to a bridge truss with an unsymmetrical load, it was a disappointment to learn that the promise of advantages previously indicated could not be realized in practice.

In 1921, a student—Mr. K. P. Bahjejian—devoted some time to an examination of Mao's methods as given in the published abstract of his thesis. He discovered the interesting fact that although the deduction of the fundamental equations is based on radically different ideas, the form of certain equations is the same as the corresponding ones in Müller-Breslau's method.

This leads to an explanation of how Mr. von Abo's paper came to be prepared in its original form. The most decisive element of the proceedings was the action of the Committee in charge of Mr. von Abo's graduate work at McGill University, of which Henry M. MacKay, M. Am. Soc. C. E., was Chairman; after completing two years of his work at that institution, the Committee recommended that Mr. von Abo spend the third year in residence at Cornell University and write his thesis there.

Since the Committee made no suggestion regarding the thesis subject and Mr. von Abo had not found any subject which made an effective appeal, he was ready to consider and then to adopt a suggestion to write on secondary stresses. This subject was suggested because of his exceptional educational preparation for the task. He had previously received four degrees: Bachelor of Arts, Bachelor of Science in Engineering, Master of Arts in Pure Mathematics, and Master of Arts in Applied Mathematics. In no case, either before or after coming to America, did he ask for advanced credit and, therefore, each degree represents full-time work in residence. It was found that his courses of study had given him excellent facility in handling advanced mathematics, a working knowledge of theories of elasticity, methods of least work or of deformation, advanced graphic statics, etc. Accordingly, he had command of all the tools necessary to handle this difficult technical subject. That a student of such character, ability, and maturity, having previously completed four years of graduate work, should be advised to take his last year in a sister university, represents a generous spirit of co-operation unparalleled in higher education.

The speaker believes that the Society deserves great credit for the publication of this paper, thus making available to the Engineering Profession in the

English language the present status of theoretical knowledge on secondary stresses, the importance of which will undoubtedly increase with the years, especially to bridge engineers.

CHARLES EVAN FOWLER,* M. AM. SOC. C. E.—The purpose in this discussion is to explain what was done at the Niagara Arch Bridge with reference to accounting for the secondary stresses. The secondary stress in a member is an increment of stress in excess of the calculated axial stress. An engineer usually has not the time to make a complete calculation of secondary stresses, and seldom has the funds with which to establish them by calculation or strain-gauge measurement. It is desirable, therefore, to have some means of approximating secondary stresses, that is, to determine what the maximum values are.

A great many secondary stress readings were made on the Niagara Bridge, of which only a few were published in the speaker's paper.† It is hoped that the complete records of those measurements may be placed on file at Society Headquarters so that all engineers may have a chance to study them.

The speaker does not deem it proper to compare measured secondary stresses at the ends of a member with the calculated stresses at the center. At Niagara, the stresses for certain members were read at the ends and also at the center under the same conditions of loading, thus giving a direct experimental comparison. The results were plotted and compared with those made on the Hell Gate Bridge, to determine a safe maximum to apply to all members.

The real purpose of computing secondary stress is to justify the use of higher unit stresses; for instance, at Niagara, instead of a unit stress of 16 000 lb., 20 000 lb. was used; and had the funds and the time sufficed to determine more closely all the stresses, that value would probably have been exceeded. The time is coming, it is hoped, when a locomotive loading such as *E*-90 will be used and when, knowing all the stresses in the bridge, the elastic limit will be used as the maximum allowable unit stress; then the exact limits to which a bridge can be loaded will be known.

According to the records the Niagara Arch as originally constructed did not close at the center of the top chord, so it was jacked apart with a small toggle at the center; actually it was jacked partly with the small toggle, and fully with the erection toggles at the end, and then a shim 1 in. thick was inserted. This introduced what might be termed a secondary axial stress in all the members of the bridge. This was very fortunate as the investigation in 1918, by jacking the top chord apart with a heavy toggle which exerted a pressure of about 700 tons, made it possible to replace the shim with a thin one, thus making the bridge almost a three-hinged arch and reduced the stresses to such an extent in the top chords and web members that the bridge would carry heavy modern loads.

A modification of this toggle was used in 1919 to take up the dead load stresses of the intermediate posts in the side spans so that the dead load in the members was entirely relieved while new reinforcing angles were being

* Cons. Civ. Engr., New York, N. Y.

† "Revision of the Niagara River Arch Bridge," *Transactions*, Am. Soc. C. E., Vol. LXXXIII (1919-20), p. 1919.

riveted to these posts. Under full load all parts then took stress uniformly, and the new parts did not have to wait until the old parts were over-stressed before they assumed their load. Strain-gauge readings were made that showed this was actually the case.

The strain gauges used were of three types; the Berry gauge which is a lever instrument; the Fuller-West, an improved lever gauge; and the Howard gauge which is a micrometer instrument and cannot be used for measuring stress under a moving load, but only for dead load, or a live load standing on the bridge. This practically disqualifies the Howard gauge for future live load stress measurements. The Berry gauge, on account of the delicate lever mechanism, was found to vibrate so much in taking impact measurements that one could only guess at the maximum readings for impact.

After some consultation with the speaker, A. H. Fuller, M. Am. Soc. C. E., proceeded to have his mechanician, Mr. West, at Lafayette College, devise an improved instrument, the Fuller-West gauge. Quite a number of these instruments have since been used, and it has been found that this gauge because of its more practical design and dial gives steady readings; in other words, when a train is running across the bridge, the dial needle will crawl up gradually to the maximum without vibration, and as the load goes off, will drop back again gradually so that it is possible to read the maximum accurately.

All engineers who are engaged in strain-gauge work will find that this gauge (although not so accurate as the mirror extensometer) will give satisfactory results for ordinary practical work. Arrangements are being made with one of the large manufacturers of instruments to put this gauge on the market, so that it will be available for general use.

The secondary stresses at Niagara were represented in the speaker's paper by diagrams* showing the percentages on the members at the panel points. No dangerous secondary stresses were found, probably on account of the fact, as Mr. Ammann has stated, that there was a re-distribution of stress when it approached the elastic limit. On the inside of the posts, curved brackets were connected with the railway floor-beams, which greatly increased the secondary stresses; it seems practically impossible to calculate such secondary stresses accurately.

Recently, in a large arch bridge, angles were provided to reinforce the edges of large gussets against secondary stresses. Readings made at the Niagara Arch on the edges of the large gussets disclosed no secondary stresses; evidently, the truss members rotate uniformly and carry the gussets with them. By taking account of secondary stresses, an engineer can feel perfectly safe, regardless of the distribution of stress, as to the total unit stresses in all members.

The late Paul Wölfel, M. Am. Soc. C. E., related an interesting case covered by some German experimenters who measured the stresses in a roof truss, in which the knee-brace ran from the post, through the bottom chord of the truss, up to the top chord. They varied the sections of these members in different experimental trusses, making each of the members in turn too small to take

* *Transactions*, Am. Soc. C. E., Vol. LXXXIII (1919–20), p. 1936.

its stress; and measuring the stresses in the various members described, it was found that the stresses were re-distributed, so that none of the members was over-stressed. That is another corroboration of the fact that secondary stresses will distribute themselves throughout the cross-section.

An engineer always desires to know the magnitude of the secondary stresses. At Niagara, there being neither the funds nor the time to make a complete calculation for every point in the truss, these stresses were determined by comparison with the Hell Gate curves superimposed on the Niagara panel points to the same relative scale, and with curves plotted from the Niagara secondary stress readings; in every case secondary stresses were used so as to be on the safe side.

One stress not considered at Niagara was the traction or braking stress from a suddenly stopped train. Account was taken of all the other stresses; but an approximation of the traction and braking stresses showed them to be relatively so small, that they were not included in the total stresses. The unit stresses were fixed at 20 000 lb. in tension, for steel with an elastic limit of more than 30 000 lb. per sq. in.

It is hoped that sometime the Society will issue a specification that will represent the superior limit of engineering knowledge. Engineers are conservative, but progress demands that in bridge specifications all factors should be included, and the unit stresses fixed accordingly.

H. M. MacKay,* M. Am. Soc. C. E.—The speaker considers this paper the most useful treatise on secondary stresses that has yet been published. The various methods of calculation are so clearly explained and so frankly compared that the reader can easily choose for himself the one best suited to his problem. It is not, however, the speaker's purpose to discuss the paper, but to deal with another phase of the question. Given the fundamental assumptions, the theory of secondary stress calculations may be regarded as well established; but there is still some doubt as to the extent to which the assumptions are valid and to which actual stresses agree with those calculated.

In all the methods of calculation explained in the paper two assumptions are tacitly made:

1.—That the members meeting at a joint are so rigidly held that the angles between their axes at the extreme ends remain constant.

2.—That between its extreme ends each member is quite free to bend and that its moment of inertia remains constant.

The first of these assumptions is dependent on the relative rigidity of the gusset-plates, connecting rivets, and members themselves. Relative rotation of the ends of members may sometimes occur. This, of course, would reduce the secondary stresses. The second assumption is never true in riveted frames. The members are under a measure of restraint, or, to put it differently, have an increased moment of inertia for some distance from their ends. This tends to increase the secondary stresses. Many other factors affect the stresses at critical sections, so that although a number of valuable measure-

* Dean, Faculty of Applied Science, McGill Univ., Montreal, Que., Canada.

ments have been made, present knowledge of actual stresses is far from complete, and any addition to the slowly accumulating data may be pertinent.

In the course of an examination of some 104 ft. 7-in., Pony truss spans for a Canadian railway (Fig. 97), the speaker made a fairly thorough survey of one-half of one truss, with a 10-in. Howard gauge, for the purpose of ascertaining the maximum stresses under a heavy type of Mikado engine then recently put into service. Gauge points were first established as close as possible to the ends of the members selected for examination. From eight to ten gauge lines were placed at each section as shown in Fig. 97, and their

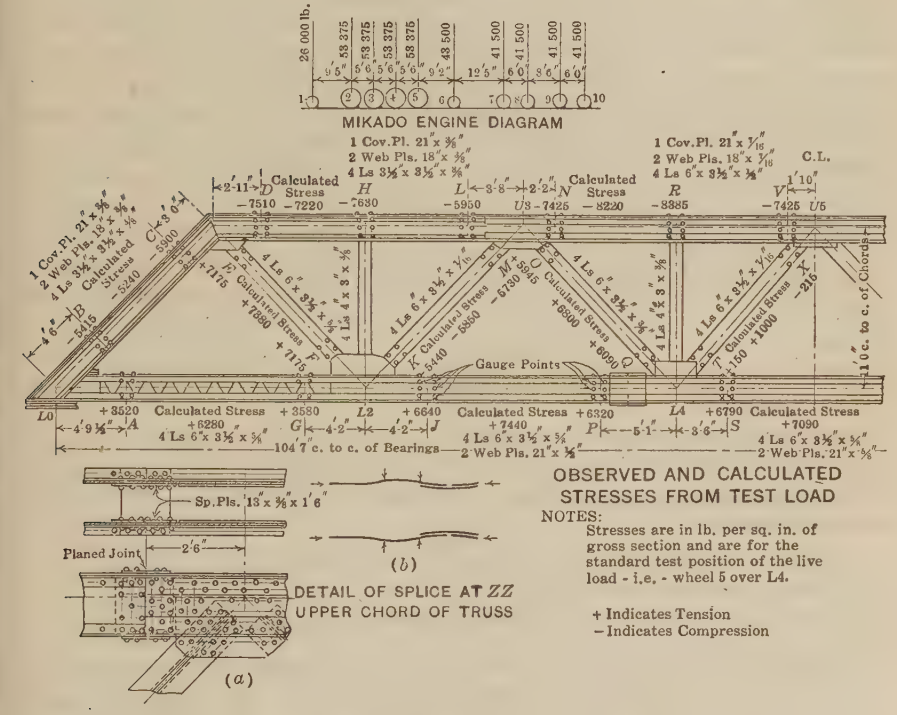

FIG. 97.

lengths measured with the span unloaded. A test train consisting of a 225-ton Mikado engine followed by two 50-ton coal cars fully loaded (Fig. 97) was then placed on the span in such a position as to give the maximum stress in the central section of the top chord, which was the principal source of apprehension. The stresses in the other important members for this position of the load were, however, not far below the maximum. The established gauge lengths were again measured and the stresses due to the static live load thus determined. Afterward, impact tests were carried out, using recording deflectometers and extensometers, but these do not concern this discussion.

Although these impact measurements brought out nothing new, they confirmed very well the principal conclusions reached by the Committee on Impact of the American Railway Engineering Association.

The speaker believes that the method here described whereby the measurement of static and dynamic effects is made separately, has much to commend it. The determination of the highest stresses existing at critical sections required the use of short gauge lengths. It is desirable to have numerous points of measurement across the section, since a planar variation of stress is a purely imaginary condition in most built-up members. Even if the recording and other extensometers and gauges available for measuring dynamic effects were entirely reliable (which is perhaps not yet fully established), it is hardly practicable to use them with such short gauge lengths, and in such numbers, simultaneously, as to give satisfactory results. On the other hand, considerable time and expense are involved in making a number of consecutive measurements by shifting the instruments and running the test train over the span repeatedly for each member measured; and it is impossible to ensure the duplication of the same conditions under repeated runs. Measurements of static stress can be made quickly, inexpensively, and, above all, reliably. A comparatively small number of determinations of the dynamic effects at convenient points will then give all the data required. The speaker would strongly urge that at least some check measurements of static stress should be made a part of every program for stress determinations in bridges. He believes that this procedure would prevent the accumulation of much data of doubtful accuracy which may becloud rather than throw light on the questions at issue.

The static live load primary stresses as calculated, and as measured, taking E as 29 000 000 lb. per sq. in., are shown on Fig. 97. The average differences between the measured stresses at the two ends of the same member were, as follows:

Bottom chords, 190 lb. per sq. in., or 3.6% of stresses measured.
Web members, 145 lb. per sq. in., or 2.3% of stresses measured.
Top chords, 840 lb. per sq. in., or 12% of stresses measured.

At the point, L, in the top chord, the stress, although the measurements were repeated and carefully checked, was abnormally low. The section of measurement was at the end of a splice plate as shown in Fig. 97(a), and it is suggested that the webs and flanges of the angles may have been affected as in Fig. 97(b). If the webs were thus bent (the angle flanges would probably be similarly affected), the fact that the gauge measurements were taken on the convex side of the bend would account for the low stresses observed. Doubtless, similar effects would occur in some degree at other points. The speaker has often noted effects of this kind in extensometer work.

Comparing the measured and calculated stresses, it appears that in the bottom chords all the measured stresses were less than those calculated. The average difference was 1 530 lb. per sq. in., or 22% of the calculated stress. The difference was greatest in the end section, 2 930 lb. per sq. in., and least

in the center section, 300 lb. per sq. in. In the web members, too, all the measured stresses were less, the average difference between calculated and measured stresses being 310 lb. per sq. in., or 5% of the average measured stress. In the top chords and end post, the measured stress was in some cases greater and in some cases less, the average difference being 570 lb. per sq. in., or 8% of the average measured stress. The mean measured stress in these members was, however, only 145 lb. per sq. in., or 2% less than the mean calculated stress.

In explanation of the great discrepancy between the observed and calculated stresses in the bottom chord, it is to be noted:

1.—That the roller bearings were inoperative.

2.—That four lines of stringers were used, the outer line being about 3 ft. 2 in. from the ends of the floor-beams.

3.—That the floor-beams were provided with 15 in. by §-in. cover-plates extending about 10 in. beyond the outer line of stringers. The floor-beams were, therefore, unusually rigid laterally. Analysis of the conditions thus set up hardly seems worth while, particularly in view of the character of the end connections of the end floor-beams. Qualitatively, however, they explain reasonably the observed stresses existing in the bottom chords. Discrepancies elsewhere may be attributed partly to local conditions, partly to uncertainties regarding the distribution of wheel loads, and partly to errors of measurement.

In calculating the secondary stresses the following adjustments were made:

1.—Measured primary stresses were used in preference to those calculated where there was a material difference between them.

2.—Inasmuch as the observed deflection at the center of the span was only 94% of that calculated on the basis of the measured stresses, all primary stresses were reduced 6% for the purpose of computing angular distortions. This it was hoped would make a reasonable allowance for the effect of details and end connections in diminishing the axial distortion of the members.

3.—Although the stresses in the verticals were not measured, the Howard gauge being unsuitable for measuring small stresses, an estimate of these stresses was made by considering the deflection produced in the top chords, and the values thus obtained, amounting to a few hundred pounds per square inch, were inserted.

4.—The end of the span rested on hardwood blocking without any hinge. An approximate analysis showed that, as might be expected, there was no close approach to fixity at this joint. In the absence at the time of any suitable means for measuring the rotation of the joint, it was impossible to calculate independently the value of the external moment. The speaker, therefore, "loaded the dice" to a certain extent by introducing the value of this moment derived from the measured secondary stresses in the adjacent members. The measured secondary stresses at this point are, therefore, in no way a check on the calculated values, except as regards the relative bending moments in the two members meeting there.

The calculated and observed stresses are shown in Figs. 98 and 99 on which the observed stresses at all gauge points are plotted on an elevation of

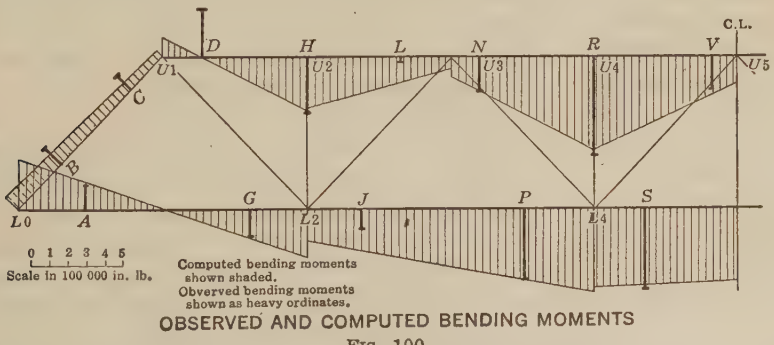
the member. The full inclined lines drawn across the diagrams show the average measured primary stress plus the calculated secondary stress; the broken lines show the calculated primary plus the secondary stress. In Fig. 100, the calculated and observed bending moments for the chord members are shown. The "observed bending moments" were deduced solely from the measured stresses in fibers near the upper and lower edges of the members, all intermediate measurements being neglected for this purpose.

Figs. 98 and 99 show that in most cases the agreement between the calculated secondary stresses is very good. A notable exception is the point, *D*, (Fig. 98) near the end of the top chord, which, according to calculations based on the usual assumptions, would be close to a point of inflection. Actually, the effect of the adjacent gusset-plate is to produce a considerable bending moment at the section of measurement. In addition, the stress distribution across the face of the member, as shown in Fig. 98, indicates that the stresses in the extreme fibers (which were used for calculating the "measured" bending moment) were affected by local bending and do not follow the general trend. At the point, *L*, where there is also a relatively large discrepancy between the calculated and measured values, the measurements were probably affected by the adjacent splice, as suggested previously in connection with the discrepancy between the measured and calculated primary stresses at this point. It may be observed from Figs. 98 and 99 that there is considerable secondary stress due to lateral bending, particularly in the diagonals. In the top chords, contrary to expectation, the lateral bending is not great, at least under a full load on the span.



OBSERVED AND COMPUTED BENDING MOMENTS

FIG. 100.

The somewhat erratic distribution of stress indicated by these measurements need not be ascribed entirely or even mainly to errors of measurement. In the somewhat rough measurements made with ordinary strain gauges reading only to 0.0001 in. considerable irregularity is indeed inevitable. It is, however, the speaker's experience that even when using instruments of precision under laboratory conditions, where every precaution is taken to preclude the possibility of serious instrumental error, the stress distribution in built-up members is, in general, far from planar across the section, and often apparently erratic, although, on the whole, checking satisfactorily with the applied loads. Even in such a simple element as an apparently straight

plate in tension, this effect is very noticeable, while in built-up members kinks in the component parts—latticing, splices, tie-plates, diaphragms, and end connections—all have their effect. The increments of stress arising in this manner may often amount to from 10 to 20% of the axial stress, and, in compression members, at least, are possibly a greater source of weakness than secondary stresses of similar magnitude, since their largest values are not necessarily confined to the ends of the members.

In the truss discussed, the chords were relatively rigid as compared with the gusset-plates, and the latter had apparently little effect on the secondary stresses. The secondary stresses in an experimental truss with relatively slender members and rigid gusset-plates were measured by the speaker's colleague, Professor H. M. Lamb, in the testing laboratory of McGill University. Sensitive mirror extensometers were used, and the measurements were made with a high degree of precision. In this case the observed and calculated primary stresses agreed very closely. The observations also showed a linear variation of secondary stress from one end of a member to the other in perfect agreement with theory. The observed values of the secondary stresses were, in general, higher than the calculated values; but an analysis taking into account the influence of the gusset-plates gave a considerably closer agreement. These two trusses were probably near the opposite extremes as regards relative rigidity of members and gusset-plates, and the data obtained from them suggest that actual secondary stresses, where the elastic limit is not exceeded, are likely to lie between the values as ordinarily calculated and those calculated by some method which takes the rigidity of the gusset-plates into account. The speaker thinks it is incorrect to conclude that, as is sometimes stated, actual secondary stresses due to rigidity of joints are necessarily less than those calculated by the usual methods.

The proper provision to make for secondary stresses, after they have been determined, is by no means an easy matter to decide. There are probably few structures that, if subjected to the full loads for which they were designed, would not show local stresses approaching or even exceeding the elastic limit of the material. In fully loaded eye-bars, for example, it is well known that such is the case. In old and overloaded structures excessive local stress must be quite common; and yet these structures may function safely for long periods. The speaker suggests that a thorough strain-gauge survey of some of these old structures would give information of great value in guiding engineering judgment as to the proper provision to make for secondary stresses generally. Tests to destruction of specially designed structures have been advocated and would be highly interesting. In such tests, however, it is difficult, if not impossible, to ascertain the effects of repeated loading, while in old structures judiciously selected the information required would be, in a measure, at hand.

GEORGE E. BEGGS,* M. AM. SOC. C. E.—It is possible to determine the secondary stresses in the member of a truss by a laboratory study of an

* Associate Prof., Civ. Eng., Princeton Univ., Princeton, N. J.

elastic model. Such a model should simulate the elastic action of the truss as nearly as possible. If the model is cut from sheet material, as celluloid or cardboard, the width of the model members should be proportional to the cube root of the moment of inertia of the actual cross-section of the truss members. The effect of gusset-plates may be closely represented.

If such a model is supported on a flat drawing board, with small steel balls between the model and the board, and with hinge and expansion bearings, as indicated in Fig. 101, the influence values for the shear and moment in any member, as 5-7, may be obtained by attaching a "deformeter gauge" to this member, by introducing in such member rotative and shear deformations and by measuring with a microscope the deflections of the load points of the structure. A full description of this method of mechanical solution is given in a discussion of the paper by A. C. Janni, M. Am. Soc. C. E., entitled "The Design of a Multiple-Arch System and Permissible Simplifications".*

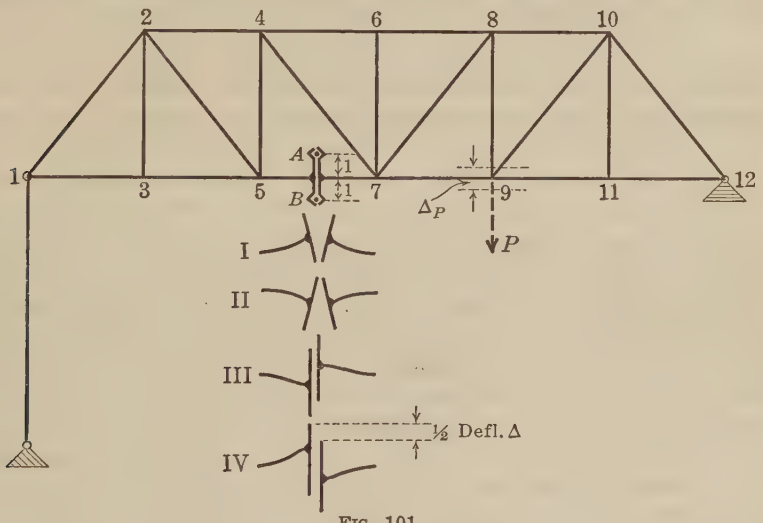


FIG. 101.

Suppose, for example, it is desired to find the bending moment at Section AB in the member, 5-7 (Fig. 101) caused by a load, P, at a panel point, 9. Introduce into the deformeter gauge plugs of unequal diameter so as to produce in the member, 5-7, at Section AB, the angular deformation indicated by Fig. 101 (I). With a measuring microscope set over a point, 9, and oriented in the direction of P, read the first deflected position of Point 9. Reserve the unequal plugs in the gauge so as to produce in the member, 5-7, the angular deformation indicated by Fig. 101 (II). Read with the microscope the new deflected position of 9. It follows from Maxwell's theorem that the bending moment in AB is given by:

$$M \text{ (foot-pounds)} = \frac{\Delta_P}{\Delta_G} \cdot P\,(m)$$

in which, Δ_P equals the component of the deflection of the load point, 9, in the assumed direction of P lb., m equals the scale of the model such that 1 in.

* *Transactions*, Am. Soc. C. E., Vol. 88 (1925), p. 1208.

equals m ft., and Δ_G is the total angular deformation in radians introduced at Section AB.

To obtain the shear at the same section, introduce into the gauge suitable plugs to produce the shearing deformation indicated by Fig. 101 (III) and (IV). Read the corresponding component deflection, Δ_P, of the load point, P. If Δ_G now represents the shearing deformation at Section AB to the same scale as that used in measuring Δ_P, it again follows by Maxwell's theorem that the shear, S, at Section AB is given by:

$$S = \frac{\Delta_P}{\Delta_G} \cdot P$$

The direct, or normal, stress in the member is most easily computed by Mechanics. The bending moment at any other section of this member, 5-7, readily follows from the known moment and shear at Section AB. For example, at a section distance, x, to the right of AB, the bending moment is:

$$M_x = M + S\,x$$

It is apparent, therefore, that the resultant fiber stresses at any section may now be determined by the familiar formula:

$$S = \frac{P}{A} \pm \frac{M\,c}{I}$$

= unit stress due to direct stress ± unit stress due to bending.

In reply to the comments of Professor Cross, a considerable number of laboratory tests of model structures has led the speaker to the following conclusion: If the deflection of an assumed load point of an elastic model, made about one-thirtieth of the full size, is so small that it cannot be measured accurately with a precise filar micrometer microscope detecting 0.00005 in. of motion of the load point, when a correspondingly accurate deformation is introduced at the section of a member by a deformeter gauge in which precise moment and shear plugs are used, the conclusion to be drawn is that, in the corresponding full-sized structure, there is a very delicate, uncertain, and probably rather unstable relationship between the value of the applied load and the value of the moment and shear which it produces. Where the model fails to register a small effect accurately here, also, does the seemingly accurate mathematics fail, and when this happens, the stress sought for is of no great practical importance.

In regard to Professor Cross' criticism about proportioning the widths of members according to the moment of inertia, the speaker has found by a considerable number of experiments with models that this is a satisfactory approximation. The manner in which the bending effects are distributed through a rigidly connected framework is dependent for the most part on the moment-of-inertia relationship.

D. B. Steinman,* M. Am. Soc. C. E.—Bridge engineers are indebted to Mr. von Abo for his excellent treatise on secondary stresses—a valuable contribution to technical literature.

* Cons. Engr., New York, N. Y.

The comparison of different methods applied to the same problem is instructive. The author's conclusion that Winkler's method (modification of Manderla's method) is to be preferred over the others for practical application agrees with the previously published conclusion of the speaker.*

For the solution of the series of simultaneous equations involved in the secondary stress computations, Mr. von Abo expresses a preference for Gauss' method of "normal equations." The speaker has always preferred that of "successive substitutions", which he believes to be more attractive to the practicing engineer. It is a slide-rule method, continuously self-checking, and self-correcting; it dispenses with formal rules of procedure; it permits curtailment of calculations after one or two substitutions if the last degree of precision is not required; and it reduces the tediousness of secondary stress computations. Actual comparisons show that the method of "successive substitutions" is more expeditious in practice and proves an effective check against errors; on the other hand incorrect results have been obtained by the method of "normal equations" without the computers becoming cognizant of their errors.†

Several of the discussors have referred to the effect of the gussets at the ends of the truss members in producing a difference between the calculated and the measured secondary stresses. A logical method for including the influence of the gussets in the analysis is to abandon the conventional initial assumption of constant moment of inertia throughout each member and to substitute the assumption of varying moment of inertia. The value of I may properly be taken as constant over the intermediate length of each member between gussets and as increasing uniformly from these points to the theoretical ends of the member. This revised assumption affects only the numerical constants in the basic moment equation; otherwise, the computation of secondary stresses is unaltered. If this modification is used, the error due to the effect of the gusset is practically eliminated. This procedure was used in the calculations for the new railway arch bridge over the Niagara River for the Michigan Central Railroad.

It has been stated that actual secondary stresses may sometimes exceed the calculated values; this will not be the case if the secondary stresses are calculated correctly. The assumption of a varying I near the ends of members is a simple correction that has been overlooked by past writers on secondary stresses.

The standard methods of secondary stress analysis described in the paper are, at best, long-winded and tedious. The need of the bridge engineer is for practical short-cuts that will quickly give approximate values of the secondary stresses at any selected points of a structure. Published treatments of secondary stresses appear to be confined to the longer, academic methods which yield a degree of precision not warranted by the accuracy of the underlying assumptions nor by practical requirements. The speaker has developed simple graphic methods which quickly give approximate values of the secondary stresses in any member without requiring a lengthy analysis covering the

* "Stress Measurements on the Hell Gate Arch Bridge," *Transactions*, Am. Soc. C. E., Vol. LXXXII (1918), p. 1073.

† *Loc. cit.*, pp. 1130–1131.

entire structure. Actual comparison of these values with the results obtained by the standard methods shows an agreement within a small percentage. This is certainly sufficiently accurate for practical purposes, and the time required is a matter of minutes instead of hours.

THOMAS C. SHEDD,* M. AM. SOC. C. E. (by letter).—Although this paper admittedly presents nothing new in the theory of secondary stress calculations it brings together under one heading, and in one language, most of the methods already proposed for determining such stresses. As a result it will be of great value to one interested in a critical study of the various methods.

In his Introduction the author states that:

"In recent specifications the tendency is to recognize the importance of secondary stresses. Higher unit stresses are properly permitted for combinations of secondary and primary stresses. This undoubtedly leads to a better distribution of metal and to a more uniform strength throughout the structure."

It will be interesting to examine these statements somewhat further. Among the most recent specifications are those of the American Railway Engineering Association, issued in 1920 and revised under date of May, 1922. These specifications have had a remarkably wide acceptance in the short time since their publication. To the end of 1922, according to a report† made to the Association, 79 railways with a combined mileage of 170 320 miles "have either adopted the A. R. E. A. Specifications in complete form or incorporated their provisions in their own specifications, or have signified their intentions of following one or the other of these courses as early as practicable." Of these 79 roads, 75 with a combined mileage of 169 690 are listed by the Interstate Commerce Commission with the 262 541 miles of Class I railroads. Thus, these specifications within a period of three years after their issuance have been accepted as authoritative for the design of bridges on 65% of the first-class railway mileage in the United States. It is not unreasonable to assume that there have been further acceptances since the preparation of the report here mentioned.

In view of this widespread use the ruling of these specifications regarding secondary stresses may fairly be taken as representing current practice in the United States. The ruling is found under "Secondary Stress",‡ Paragraph 47, and reads as follows:

"Designing and detailing shall be done so as to avoid secondary stresses as far as possible. In ordinary trusses without sub-paneling, no account usually need be taken of the secondary stresses in any member whose width measured in the plane of the truss is less than one-tenth of its length. Where this ratio is exceeded, or where sub-paneling is used, secondary stresses due to deflection of the truss shall be computed. The unit stresses specified in Article 38 (16 000 lb. per sq. in. basic) may be increased one-third for a combination of the secondary stresses with the other stresses, but the section shall not be less than that required when secondary stresses are not considered."

* Asst. Prof., Structural Eng., Civ. Eng. Dept., Univ. of Illinois, Urbana, Ill.

† *Bulletin*, Am. Ry. Eng. Assoc., October, 1923, p. 4.

‡ "General Specifications for Steel Railway Bridges 1920," Am. Ry. Eng. Assoc., Second Edition.

A clause identical in meaning and nearly identical in wording is included in the Final Report on Specifications for Design and Construction of Steel Railway Bridge Superstructure,* presented by the Special Committee on Specifications for Bridge Design and Construction of the Society, and also in the Final Report on Specifications for Design and Construction of Steel Highway Bridge Superstructure† by the same Committee. As further evidence of the recent tendency to recognize secondary stresses, it may be mentioned that the Standard Specifications for Steel Highway Bridges adopted by the American Association of State Highway Officials and published by the U. S. Department of Agriculture,‡ contains a clause similar to that of the reports of the Special Committee of the Society except that the allowable increase in unit stress when secondary stresses are included with other stresses is 30% instead of 33⅓ per cent.

In contrast with the specifications mentioned—which require that secondary stresses be computed in certain cases—are the 1917 Specifications of the New York Central Lines which, without qualification, definitely require that secondary stresses be computed; Paragraph 48 reads:

"The secondary stresses in truss members due to rigidity of joints and the deflection of the truss shall be computed. The unit stresses in Paragraph 41 (18 000 lb. per sq. in. basic) may be increased one-third for a combination of the axial stresses and the above mentioned secondary stresses. Stresses due to eccentricity of transverse bending shall be computed. * * * For a combination of axial stresses and stresses due to eccentricity and transverse bending the unit stresses in Paragraph 41 shall not be exceeded."

Somewhat less definite than the others, but nevertheless showing the present tendency, are the 1916 Specifications of the Pennsylvania Railroad which, in Paragraph 24, require that: "All bending and other secondary stresses in addition to direct stress are to be provided for."

These clauses, cited from various specifications, not only clearly support the author's statement regarding the tendency of recent specifications to recognize the importance of secondary stresses, but seem to indicate that the majority of railroad bridges in the United States are now designed under specifications definitely requiring more or less consideration of such stresses.

The other statements by the author, namely, that "higher unit stresses are properly permitted for combinations of secondary and primary stresses", and that "this undoubtedly leads to a better distribution of metal and to a more uniform strength throughout the structure", should be considered together.

It does not seem that current specifications offer much support to this thesis. It is true that all the specifications cited—with one exception—permit an increase in the allowable unit stress of one-third (30% in one case), but—with the same exception—they include a qualifying clause which in substance requires that "the section shall not be less than that required when secondary stresses are not considered."§ The result is that unless the secondary

* *Transactions*, Am. Soc. C. E., Vol. LXXXVI (1923), p. 471.

§ "General Specifications for Steel Railway Bridges, 1920," Am. Ry. Eng. Assoc., Second Edition.

stress exceeds 33⅓%, there is no change whatever in the distribution of the metal and the strength of the structure is no more uniform than if secondary stresses had not been considered.

It is this feature of current specifications which seems objectionable to the writer. In the case where secondary stresses have been computed, the tendency will be to assume that the structure has a better distribution of metal and a more uniform strength than in the opposite case—an assumption which is not supported by the facts. It is true, of course, that some metal may have been added at the points of high secondary stress, but the fact remains that some members having little or no secondary stress will be working at the basic unit stress while others will have a unit stress varying from the basic value to a value one-third higher. The result is a structure which does not have uniform strength; some members are wastefully proportioned, or else other members are over-stressed, depending on whether or not the basic stress be considered too high. This is not necessarily a dangerous condition (if it is, most of the bridges now in operation are in a dangerous condition). The danger is that engineers will convince themselves by the multiplicity of their calculations and the complexity of their analyses that they have greatly improved their structures. They may know more about the actual stress conditions, which is very desirable, but it is certain that by complying with specifications as at present written they will have done little toward securing greater uniformity of strength.

In the 1916 Specifications of the Pennsylvania Railroad, the clause dealing with secondary stresses (Paragraph 24 quoted previously) is not definite, but the writer understands that where secondary stresses are included with primary stresses the allowable intensity of stress is not increased. This is the correct method of design. If secondary stresses are calculated and included with primary stresses in an effort to secure a better distribution of metal the same unit stress must be used in all members whatever the amount of secondary stress. Whether that unit stress should be the one now in common use or a higher one is entirely another question. The writer believes that when the problem of secondary stress has been thoroughly analyzed higher unit stresses may properly be permitted.

Emphasis should be placed on the matter of thorough analysis. If secondary stresses are to be added to primary stresses both must be simultaneous; this involves the question of whether the maximum primary stress combined with the simultaneous secondary stress will be greater than the sum of some other greater secondary stress combined with its simultaneous primary stress. The problem does not have an obvious answer, and its solution requires extensive calculations.

Assuming, however, that the necessary computations have been made, there are still many problems. All the methods thus far proposed for the determination of secondary stresses assume, for a given member, a constant moment of inertia from intersection to intersection. This is obviously not the case; for heavy trusses with large, thick, or multiple gussets and outside splice-plates at the connections, the error becomes considerable. Correcting for this condi-

tion by the method suggested in an interesting paper by O. H. Ammann,* M. Am. Soc. C. E., there still exists the uncertainty of the distribution of stress (secondary and primary) in the joints—about which practically nothing is known at present. Many engineers are of the opinion that this question is one which cannot be solved.

It is not apparent that the inclusion of secondary effects increases the uncertainty already existing in a discussion of joints with respect to primary effects. If the methods of joint analysis (crude though they are) are extended to include secondary effects, it would seem justifiable to assume that at least as much is known as though secondary effects had been disregarded. If that is correct then this uncertainty, serious though it is, should not be considered an impassable barrier to improvement in design by a consideration of secondary stresses.

At present little is known as to how the consideration of secondary stresses will affect the economics of design and construction. Should such stresses be reduced by placing restrictions on the ratio of width to length of members, and if so, should the length be defined as the distance between intersection points or the clear distance between joint plates? Is it proper to ignore the secondary stresses if the limiting ratio is met, and if not should they be eliminated, either partly or entirely, by adjustments of lengths of members and angles between them, or should additional metal be provided to keep the maximum stresses within the prescribed basic stress? Which method leads to the structure having the greatest strength and wearing qualities for the quantity of metal used, and which to the greatest ultimate economy?

The writer is a firm believer in thorough-going studies of secondary stresses, but holds that investigation and discussion of the problems just mentioned is the immediate need rather than the further elaboration of the mathematics of analysis.

Hardy Cross,† M. Am. Soc. C. E. (by letter).—The author has done a very careful piece of work and has succeeded in stating with admirable clearness the standard methods for the computation of secondary stress. It is well that so comprehensive a statement is now available in American literature. The author's opinions as to the relative advantages of the different methods are of value, moreover, on account of his familiarity with all of them, for the writer has found that current statements as to the advantages of any one method are too often supported by complete ignorance as to all others.

In such computations, most engineers will combine from the standard methods those features which appeal to their individual tastes. The writer prefers algebraic methods of analysis; for structures with a large number of panels they are almost necessary as checks on graphic solutions. In using Mohr's method, therefore, he computes the rotation angles for the bars of the statically determinate truss. These may be easily found from the angle changes as computed by Manderla. It is to be noted that the true rotations are not required, but only relative rotations with reference to any bar, such as the

* *Engineering News-Record*, October 23, 1924, p. 666.

† Prof., Structural Eng., Univ. of Illinois, Urbana, Ill.

center vertical, which is assumed to stand fast. If the changes of angle have been independently computed, this gives a complete check on the values of ψ.

The writer thinks the author does not give due prominence to the methods of successive approximation. For large trusses with many panels these seem decidedly the most practical of all, if not the only possible ones for office use. In this connection the author has omitted from his bibliography two interesting *Bulletins* of the University of Minnesota,* which deal with successive approximations by Mohr's method. A method apparently almost identical with this has resulted from Swiss studies.† Although this method is said to be new, in its essentials it does not appear to be so. It is self-checking, converges with a reasonable number of approximations, and has a decided advantage in that the work can be picked up and carried on in spite of frequent interruptions. A method which requires uninterrupted attention is difficult to use in an office. The convergence has been sometimes misrepresented, the variations in successive values of ϕ at any point being shown, whereas it is successive values of $(\phi - \psi)$, which are really significant.

Mao's analytical method is essentially the same as Müller-Breslau's, but complicated by the use of an unnecessary unwieldy and unfamiliar paraphernalia; the author is correct in discarding it. Müller-Breslau's method, however, is quite comparable, in simplicity and ease of application, with those of Manderla or Mohr. The modification of considering all clockwise moments as positive adds to its practicalness. The writer has used it for some years with modifications as explained herewith.

The author's Equations (47), (48), and (49) may be rewritten, as follows:

$$\rho_4 = 2(\rho_1 - \rho_2 + \rho_3) - \rho_1 \pm (-6E\Delta\alpha) \quad \ldots\ldots\ldots\ldots (47a)$$

$$\rho_5 = 2(\rho_1 - \rho_2 + \rho_3) - \rho_2 \pm (-6E\Delta\alpha + 6E\Delta\beta) \quad \ldots\ldots\ldots\ldots (48a)$$

$$\rho_6 = 2(\rho_1 - \rho_2 + \rho_3) - \rho_3 \pm (+6E\Delta\beta) \quad \ldots\ldots\ldots\ldots (49a)$$

The alternative signs before the angle changes will be taken as positive in those triangles in which the succession, ρ_1, ρ_2, ρ_3, etc., is clockwise, but reversed in those triangles in which the succession is anti-clockwise.

Now this re-arrangement makes possible a systematic computation of successive values in terms of ρ_1 and ρ_2. Moreover,

$$\rho_1 - \rho_2 + \rho_3 = \rho_4 - \rho_5 + \rho_6 \quad \ldots\ldots\ldots\ldots\ldots\ldots (119)$$

which gives a repeated check on the additions.

Again, in a symmetrical truss, all the ρ's on the left may be expressed in terms of ρ_1 and ρ_2 and all the ρ's on the right in terms of ρ_{42} and ρ_{41} (Fig. 52), the corresponding values of ρ at the other end of the truss. In corresponding ρ's, all but the constants will be identical on the two sides of the truss. The values of ρ_1, ρ_2, ρ_{42}, and ρ_{41}, will then be determined by four equations at the center, still using the notation of Fig. 52 namely:

$$\rho_{21} \text{ left} = \rho_{21} \text{ right}$$

$$\rho_{22} \text{ left} = \rho_{22} \text{ right}$$

* *Bulletins 2 and 4*, Engineering Studies, Univ. of Minnesota.

† "Secondary Stresses in Steel Riveted Bridges," O. H. Ammann, M. Am. Soc. C. E., *Engineering News-Record*, October 23, 1924, p. 666.

$$M_{20} + M_{21} + M_{23} = 0$$
$$M_{17} + M_{16} + M_{22} + M_{26} + M_{27} = 0$$

The first two will be found to be equations in $(\rho_1 - \rho_{42})$ and $(\rho_2 - \rho_{41})$ and the last two, equations in $(\rho_1 + \rho_{42})$ and $(\rho_2 + \rho_{41})$, thus furnishing two pairs of simultaneous equations which are easily solved.

When the values of the end ρ's have been determined, they may be substituted in the expressions already found, as the author himself has done (page 81). It is, however, quicker to use again Equations (47*a*), (48*a*), and (49*a*), and carry these values through from each end to an absolute check by the four equations indicated at the center.

The writer finds convenient a form as indicated in Fig. 102 and Table 34. The values are taken in many cases from the author's computations; the checks are not always absolute, although the discrepancies are small.

Fig. 102 shows the position of the ρ's and thus the order in which they are taken up in Table 34. It will be noted that they are slightly different from the author's Fig. 52. ρ_{13} is repeated after ρ_{14}, as the computation here "backtracks" to get to ρ_{15}, and so around the triangle. The signs in Fig. 102 indicate whether the signs of the angle changes are to be taken as computed or are to be reversed.

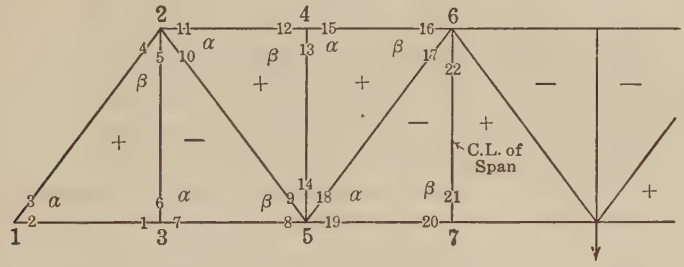

Fig. 102.

The procedure here indicated presents the following advantages:

1.—It systematizes both the writing and the solving of the equations in Table 8.

2.—It adapts the work to the use of a calculating machine.

3.—It gives as the work proceeds an absolute check on all equations.

4.—It reduces the number of equations, and lessens the labor of their solution more than one-third.

5.—It simplifies the labor of evaluation shown in Table 9, if the values found are "carried through" by the routine indicated. This also presents an absolute check on the work.

In sub-divided panels and similar cases it is necessary to introduce temporarily a third unknown which is evaluated by balanced moments in that panel. Four-sided figures such as occur in sub-divided trusses and in *K*-trusses may be solved by introducing a false member or by writing special equations. Müller-Breslau's method, however, is not so convenient in this very important group of cases as that of Mohr or Manderla.

$$\rho_1 - \rho_1' = + 8.3920 \qquad \rho_2 - \rho_2' = - 147.5939$$
$$\rho_1 + \rho_1' = - 22.3734 \qquad \rho_2 + \rho_2' = + 56.3987$$

$$\rho_1 = - 6.9907;\ \rho_1' = - 15.3827;\ \rho_2 = - 45.5976;\ \rho_2' = + 101.9963$$

*These values of ρ are obtained from equations of balanced moments at the joints, these being the first five and last five equations indicated by the author (see p. 79).

† These values are the sum of the first and last less the middle one of the three values just preceding.

‡ The word, "check", indicates that a check is here applied to the summation, as indicated in Equation (119). This check is absolute on the continued summation, but not on the solution by moments for the values of ρ. The latter may be checked by assuming any convenient values, such as 10 for ρ_1 and ρ_2, and then testing the equation, $\Sigma M = 0$.

Further simplification is also possible by rounding off the values of K and of the angle changes. In this particular case, the K-values for Members 2-4, 4-6, 6-8, 8-10, may well be taken as unity and the others in proportion, these ratios being rounded off to two places of decimals. Evidently, it is the K-ratios and not their absolute values which are significant in the equations. It is also evident that these ratios and the angular changes need not be computed with great precision provided exactly the same values are always used for

the same terms. If this were not the case a slight difference from the computed value of the area or moment of inertia of a bar would upset the results to such an extent as to make all secondary stress computations futile.

This indicates another field of investigation. Neither the length of member to be used in calculating the distortions of the truss, nor the length involved in the secondary distortion, is known with accuracy. It remains to be determined to what extent these uncertainties affect the values of the secondary stresses; it may be that only a roughly approximate solution is justifiable, in which case the method of successive approximations has even greater advantages. While, therefore, the mathematical theory of secondary stresses is quite complete and little more is to be expected from its elaboration, there is still room for systematizing the computations and especially for simplifying them by approximations and for determining what degree of approximation is desirable or permissible. The writer believes that, in general, any relative advantages of the methods of Manderla, Mohr, and Müller-Breslau, when these methods are carried out in full, are largely illusory, but it does appear that Müller-Breslau's method is very readily systematized while the first two—which are practically identical—are more readily adapted to successive approximation.

Whatever is done, the computation of secondary stresses will remain a strenuous pursuit and at the end of the chase one faces the problem of what to do with the quarry. The cases will probably not be numerous in which forcible measures of elimination are justified. In other cases, evaluation gives some idea of possible points of weakness. High secondary stresses may then be reduced by revising the make-up of the members or by such devices as adjusting hangers and idle struts. The writer, however, believes that it is not practicable at present to effect a better distribution of metal by designing for the total stress (using generally increased basic stresses) rather than for the primary stress. The following uncertainties bear on the question:

(*a*) Secondary stresses in tension members are probably less serious than in compression members;

(*b*) Secondary stresses in compression members are less serious when there is double flexure (with a point of contraflexure in the member) than otherwise and they may even be beneficial in such cases in that they retard buckling;

(*c*) Secondary stresses are often less dangerous than primary stresses because of their localization, this being especially true when secondary moments in two planes are combined;

(*d*) Present knowledge of impact effects on secondary stresses is much less than in regard to primary impact, inadequate as are the data on the latter; perhaps secondary stresses tend to dampen vibrations and an unformulated knowledge of this supports the structural engineer's preference for "stiff" structures in spite of their secondary stresses.

These statements, however, should not be taken to indicate any doubt as to the growing importance of a thorough understanding by bridge engineers of the nature, approximate theoretical value, and general theory of secondary stresses in bridge trusses; but the same importance attaches to the study of

secondary stresses due to the deformation in the frames of steel buildings and in other cases. There is, at present, a decided swing toward more elaborate analyses in both steel and concrete structures; the requirement in the new specifications for concrete of the Joint Committee on Standard Specifications for Concrete and Reinforced Concrete* that bending stresses shall be computed in the columns of concrete buildings, even in the face of uncertainties more pronounced than those outlined herein, is an instance in point. All this is very well as long as it is understood that such analyses merely indicate danger points. Elaborate analyses alone, however, will not justify a general increase in fiber stress; the relation of secondary stresses to the factor of safety is a much more intricate problem than their mathematical formularization or evaluation.

The writer is surprised that Professor Beggs is able, by the use of his models, to easily and accurately determine secondary stresses. As secondary stress depends on the area as well as the stiffness of the member, it would seem that it could not, in general, be found by use of a uni-planar model. Moreover, the direct stresses produced in a model loaded as he suggests must be extremely small, and, therefore, the truss deflections, which are a result of the direct stresses alone, must be difficult to measure at all.

If, by rotation of the cut ends of a member, the ends of an outer fiber are displaced one unit relative to each other, the deflections will be influence ordinates for the fiber stress. If the rotation is around the neutral point of the section, the influence line is for the stress due to the moment only; if about the kern point, it is for the total stress. Since in this instance the direct stresses are relatively large, the centers of rotation must be located with surprising precision; and, for similar reasons, the shear must have been applied along a line very precisely normal to the axis.

W. M. Wilson,† M. Am. Soc. C. E. (by letter).—The Engineering Profession is indebted to the author for presenting, in a form for comparison, the various methods that have been developed for computing the secondary stresses in the members of a truss due to axial deformations. The selection of a method usually embodies an accidental element of considerable importance for, with most engineers, the first method that has been mastered and systematized seems better than a new one and is likely to be retained, even if the new method may be superior.

The writer prefers the method that the author has designated as Mohr's semi-graphical method. This is certainly the easiest to understand and, as indicated by the author, is as short as any. Moreover, each operation can be checked as it is performed, thus eliminating costly errors that might otherwise be undetected until revealed by equating the sum of the moments at a panel point to zero. Furthermore, the extensions can be made with sufficient accuracy by a 20-in. slide-rule. Nor will the writer concede that the graphical work (Williot diagram) introduces errors large enough to be objectionable; he has used the method extensively and has supervised its use on work where a high degree of accuracy was necessary, and has not found it wanting.

* *Proceedings*, Am. Soc. C. E., October, 1924, Papers and Discussions, pp. 1204–1206.

† Research Prof., Structural Eng., Univ. of Illinois, Urbana, Ill.

In introducing his graduate class in advanced stress analysis to the subject of secondary stresses, for the first problem the writer required the nine students to determine the secondary stresses at both ends of all members of a structure consisting of a single triangle, *ABC*. The moments computed for the ends of the members are listed in Table 35. It is realized that the problem, as problems in secondary stresses go, is simple. Moreover, the results obtained by the various students do not agree very closely in some cases; but, considering that, in each case, the student was working his first problem in secondary stresses and using his own Williot diagram, the discrepancies are not large. Moreover, the students who obtained answers differing most from the average also failed to obtain summations of moments at the panel points equal to zero. Inasmuch as a failure to obtain equilibrium is due entirely to inaccuracies in the arithmetical work rather than in the graphical part of the solution, the latter cannot be charged with all the discrepancies in Table 35.

Recently, the writer was engaged by a firm of consulting engineers to compute secondary stresses. Knowing that he used the semi-graphical method, the firm, unknown to him, submitted the same structure for analysis to another engineer who uses an algebraic method; the firm redeemed itself for whatever breach of ethics it may have committed by reporting to the writer that the secondary stresses, as computed by the algebraic method, agreed almost exactly with those obtained by the writer using the Mohr semi-graphical method.

TABLE 35.—Secondary Moments in Triangular Frame.

Moment.	Student No.								
	1.	2.	3.	4.	5.	6.	7.	8.	9.
M_{AB}	−285 000	−290 000	−288 000	−288 000	−284 000	−300 000	−286 000	−286 200	−291 600
M_{AC}	+293 400	+291 000	+291 000	+291 600	+302 400	+284 000	+283 200	+288 300	+290 700
M_{BA}	−642 000	−651 000	−648 000	−648 000	−649 200	−654 000	−656 000	+645 800	−648 600
M_{BC}	+655 600	+651 000	+653 000	+648 000	+652 500	+655 200	+652 000	−646 200	+650 400
M_{CB}	+169 200	+175 000	+176 500	+172 800	+174 000	+190 800	+168 000	+174 400	+175 000
M_{CB}	−169 000	−175 000	−174 500	−172 800	−178 800	−174 600	−171 000	−174 600	−174 600

As another example cited to establish the accuracy of Mohr's semi-graphical method, the writer had the secondary stresses in a five-panel Pratt truss computed by two methods, as follows: Method 1, by determining the secondary stress at a certain point due to the primary stress in some one member, all other members being unstressed; likewise determining the secondary stress at the same point due to the primary stress in each of the other members considered separately; and Method 2, by determining the secondary stress at the specified point when all members are stressed simultaneously. Barring inaccuracies in the work, the sum of the separate secondary stresses obtained by Method 1 will equal the secondary stresses obtained by Method 2.

The secondary stresses were computed for thirty-six points, one at each end of all the eighteen members, with the following results: The difference between

the secondary stresses obtained by the two methods in no case exceeds 3% of the total; at two points, the difference exceeded 2% and was less than 3% of the total; at four points, the difference exceeded 1% and was less than 2% of the total; at thirty points, the difference was less than 1 per cent. The differences exceeding 2% occurred at points where the secondary stress was very small, being less than 1½% of the maximum secondary stress; the differences exceeding 1% occurred at points where the secondary stress is less than 20% of the maximum secondary stress. The degree of accuracy attained is thus much greater than is necessary. The writer's experience, not only in the cases cited, but in many others as well, has convinced him that the method is accurate enough for all practical purposes. The Williot diagrams, however, must be carefully drawn.

The cross-frame treated by the author* is a special case of the rectangular frame and may be solved by the equations that have been developed for rectangular frames in general.†

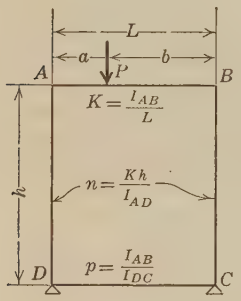

Fig. 103.

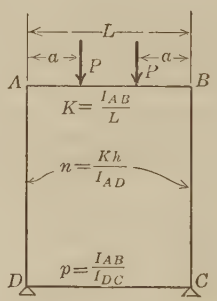

Fig. 104.

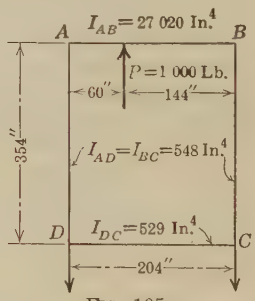

Fig. 105.

For the frame represented by Fig. 103, symmetrical about a vertical center line, but loaded unsymmetrically:‡

$$M_{AB} = -\frac{1}{2}\left\{ C_{BA}\left[\frac{2n+3p}{\alpha} - \frac{1}{\beta}\right] + C_{AB}\left[\frac{2n+3p}{\alpha} + \frac{1}{\beta}\right]\right\}$$

$$M_{BC} = -\frac{1}{2}\left\{ C_{BA}\left[\frac{2n+3p}{\alpha} + \frac{1}{\beta}\right] + C_{AB}\left[\frac{2n+3p}{\alpha} - \frac{1}{\beta}\right]\right\}$$

$$M_{CD} = \frac{1}{2}\left\{ C_{BA}\left[\frac{n}{\alpha} - \frac{1}{\beta}\right] + C_{AB}\left[\frac{n}{\alpha} + \frac{1}{\beta}\right]\right\}$$

$$M_{DA} = \frac{1}{2}\left\{ C_{BA}\left[\frac{n}{\alpha} + \frac{1}{\beta}\right] + C_{AB}\left[\frac{n}{\alpha} - \frac{1}{\beta}\right]\right\}$$

in which,

$$\alpha = n^2 + 2pn + 2n + 3p$$

$$\beta = 6n + p + 1$$

* See pp. 127–143.

‡ *Loc. cit.*, p. 107.

n = ratio of K (moment of inertia divided by length) of top member to K of left-hand column, for a rectangular frame.

p = ratio of K of top member to K of bottom member for a rectangular frame.

M_{AB} = moment at End A of Member A-B.

M_{BC} = moment at End B of Member B-C.

M_{CD} = moment at End C of Member C-D.

M_{DA} = moment at End D of Member D-A.

C_{BA} = moment at End B of Member A-B, due to any system of loads, when A and B are on the same level and when the tangents to the elastic curve at A and B are horizontal.*

C_{AB} = moment at End A of Member A-B.

For a frame symmetrical about a vertical center line and supporting loads symmetrical about the same center line, the condition usually found in practice, the moments are given by the equations:

$$M_{AB} = M_{BC} = -C_{AB}\frac{2n + 3p}{\alpha}$$

$$M_{CD} = M_{DA} = C_{AB}\frac{n}{\alpha}$$

In these equations, C_{AB} and C_{BA} are functions of the loads. For the single load shown in Fig. 103, $C_{AB} = \frac{P a b^2}{L^2}$† and $C_{BA} = \frac{P a^2 b}{L^2}$. For the two symmetrically spaced equal loads of Fig. 104,

$$C_{AB} = C_{BA} = \frac{P a}{L}(L - a).$$

For the problem solved by the author, illustrated by Fig. 105:

$I_{DC} = 529$ in.^{4} $\quad L = 204$ in.

$I_{AB} = 27\ 020$ in.^{4} $\quad h = 354$ in.

$I_{BC} = I_{AD} = 548$ in.^{4} $\quad a = 60$ in.

$P = -1\ 000$ lb. $\quad b = 144$ in.

$$K = \frac{27\ 020}{204} = 132.451 \text{ in.}^3$$

$$n = 132.451 \times \frac{354}{548} = 85.561$$

$$p = \frac{27\ 020}{529} = 51.078$$

$$C_{AB} = \frac{-1\ 000 \times 60 \times 144 \times 144}{204 \times 204} = -29\ 896 \text{ in-lb.}$$

$$C_{BA} = \frac{-1\ 000 \times 60 \times 60 \times 144}{204 \times 204} = -12\ 456 \text{ in-lb.}$$

$$\alpha = 85.561^2 + 2 \times 51.078 \times 85.561 + 2 \times 85.561 + 3 \times 51.078$$
$$= 16\ 380$$

* Values of C for various loads are given in *Bulletin No. 108*, Eng. Experiment Station, Univ. of Illinois, pp. 24, 26.

† See *Bulletin No. 108*, Eng. Experiment Station, Univ. of Illinois, pp. 24, 26.

$$\beta = 6 \times 85.561 + 51.078 + 1 = 565.444$$

$$\frac{2n + 3p}{\alpha} = \frac{2 \times 85.561 + 3 \times 51.078}{16\,380} = 0.01980$$

$$\frac{1}{\beta} = \frac{1}{565.444} = 0.001769$$

$$\frac{n}{\alpha} = \frac{85.561}{16\,380} = 0.005223$$

$$M_{AB} = -\frac{1}{2}\Big[-12\,456\,(0.019802 - 0.001769) - 29\,896\,(0.019802 + 0.001769)\Big] = 434.6 \text{ in-lb.}$$

$$M_{BC} = -\frac{1}{2}\Big[-12\,456\,(0.019802 + 0.001769) - 29\,896\,(0.019802 - 0.001769)\Big] = 403.8 \text{ in-lb.}$$

$$M_{CD} = \frac{1}{2}\Big[-12\,456\,(0.005223 - 0.001769) - 29\,896\,(0.005223 + 0.001769)\Big] = -126.0 \text{ in-lb.}$$

$$M_{DA} = \frac{1}{2}\Big[-12\,456\,(0.005223 + 0.001769) - 29\,896\,(0.005223 - 0.001769)\Big] = -95.2 \text{ in-lb.}$$

The writer made the extensions with a 20-in. slide-rule and the results are in almost exact agreement with those obtained by the author using Mohr's method.

For a cross-frame having two equal symmetrically spaced loads (the usual condition), the computations are very short and simple. Using the same frame as before, but considering two loads, each equal to 1 000 lb., the computations are as follows:

$$M_{AB} = M_{BC} = -C_{AB}\frac{2n + 3p}{\alpha}$$

$$M_{CD} = M_{DA} = C_{AB}\frac{n}{\alpha}$$

in which,

$$C_{AB} = \frac{Pa}{L}(L - a) = \frac{-1\,000 \times 60}{204} \times 144 = -42\,350 \text{ in-lb.}$$

As previously determined:

$$\frac{2n + 3p}{\alpha} = 0.01980$$

$$\frac{n}{\alpha} = 0.005223$$

Substituting these quantities in the equations for the moments, gives:

$$M_{AB} = M_{BC} = 42\,350 \times 0.01980 = 838.3 \text{ in-lb.}$$

$$M_{CD} = M_{DA} = -42\,350 \times 0.005223 = -221.2 \text{ in-lb.}$$

These computations are so short and simple and the secondary stresses in the cross-frame are so important that the omission of the calculations for secondary stresses from the design seems hard to justify even in structures of moderate size.

The equations used by the writer and by the author are equivalent; the writer believes, however, that his form* is the more convenient for the designer.

THOMSON E. MAO,† ESQ. (by letter).—The writer desires to pay his highest respects to the author for the exhaustive treatment of the subject and the splendid presentation of the writer's graphic and analytic methods for the solution of secondary stresses. As far as the writer knows the paper is the most complete study of secondary stresses in the English language, and yet is not too mathematical for perusal by busy engineers in practice. The author is to be congratulated for this painstaking work, for unless a person has studied the subject deeply and actually solved some examples he cannot really appreciate the amount of time and patience required to prepare such a comprehensive paper. This work appeals particularly to the writer, who was, for some time, completely "immersed" in the subject of secondary stresses and has longed to find a companion who would have exactly the same taste and interest in such an unpopular and "lonely" subject. From the fact that secondary stresses are bound to be a factor in design, the author also deserves the appreciation of the Engineering Profession at large, as he has again proved at great expense of time and labor that, after all, this important branch of stress computation could not well be taken care of by the "factor of ignorance."

This discussion will largely deal with the two methods introduced by the writer in 1919 and described in the paper. Quoting from the preface to the writer's printed thesis:

"The methods for computing secondary stresses have been greatly improved in recent years. Two objections, however, still remain: First, the amount of time involved is often excessive, and, second, the lack of a systematic checking device by which the correctness of the various steps of procedure may be ensured. While there are numerous other defects, these two alone are generally sufficient to reduce their practical utility. Ever since the beginning of 1917, when the writer undertook the analysis of secondary stresses in a two-hinged arch, the results of which have been published in the *Transactions* of the American Society of Civil Engineers, Vol. 82, p. 1104, it always occurred to him that there must be some method which is not only shorter and less cumbersome than the current ones but which also admits of a check. For two and a half years he had worked on the subject almost incessantly, striving to find some new method that will accomplish both the above mentioned results. At last, much to his satisfaction, the graphic method of deformation contour was obtained, which not only takes less time and checks itself, but also gives remarkably accurate results. Along with this method, almost contemporaneously, the analytic method was evolved."

* Presented in *Bulletin No. 108*, Eng. Experiment Station, Univ. of Illinois.

† Pres., Conservancy Eng. Coll., Nanking, China.

It may be helpful to enumerate here the important advantages of these methods as compared with others.

Features common to both methods are:

(1) No simultaneous equations involving more than two unknowns are required.

(2) Both methods deal with a quantity which is of the same dimensional degree as the secondary stress itself. This gives more accurate results than when using a quantity involving large multiples of f.

(3) They take much less time than the ordinary methods.

(4) There are a number of checks available, especially for the graphic method.

(5) They can be easily applied to influence lines of secondary stresses.

(6) The complete information is contained in only one sheet of paper, including the rough computations, calculations, data, and formula.

Special features of the graphic method are:

(*a*) It is strictly graphical. From beginning to end no computations are required.

(*b*) It gives a complete representation of secondary stresses in every member of the truss.

(*c*) It not only shows secondary stresses at the two ends of a member, but also the variation of the stress along its whole length.

(*d*) It gives the point of inflection in a member and also the form in bending.

(*e*) With the aid of the force diagram for secondary stress lines it shows how the secondary stresses are affected by changing the section moduli of the members.

(*f*) It is more accurate than the ordinary analytic methods if the latter be computed by the use of a slide-rule. This is due to the fact that in analytic expressions the secondary stress is often found from the difference of two large numbers which must be very accurate, since the difference is small.

(*g*) The errors made in locating the base lines and vertex lines are not cumulative, as the effect of one line on the other is very small.

(*h*) It has a sufficient number of checks at every step of the procedure.

Characteristics of the analytic method are:

(1) In bridge offices where a large number of standardized trusses are to be analyzed for secondary stresses, the truss diagram, together with the small tables, could be blue-printed.

(2) This method is semi-graphical in that it shows the stresses at the proper places and their effects on each other.

(3) The entire process is mechanical. Every figure has a definite space; every procedure has a definite order.

(4) No figure is to be recorded twice and no necessary figures are omitted.

(5) All rough computations are shown on the diagram, thus rendering possible a check at any future time.

(6) The figures on the diagram are arranged so that all the additions and subtractions do not involve more than two lines of figures and can be accomplished without the use of extra paper, as when three columns of figures are to be added, etc. All the other computations can be made on a slide-rule.
(7) The method is capable of affording any degree of accuracy which may be desired.
(8) Practically all back references are eliminated.
(9) It has a unique check of secondary stresses as soon as they are found.

As explained in the paper both of the writer's graphic and analytic methods depend on two fundamental equations. The derivation of the deformation equation, as given in the writer's thesis, is criticized by the author as being unnecessarily complicated, but the writer's aim was to derive it from Mohr's work equation with the hope that it might convey more physical meaning than a pure mathematical analysis. It appears complicated because it starts from the very beginning of the theory, but the principle involved is believed to be very simple, as the author agreed.

The author also complains about the descriptions of the methods as being inevitably too long. This is due to the fact that many novel processes and features are introduced. Should some of the processes be already known to the engineers, there would not be so much explanation necessary. It can be easily seen that in Mohr's method, if one is not familiar with the Williot diagram or the Gauss solution, much more description would have been necessary to complete the paper. The writer has aimed in the methods to systematize the procedure as much as possible, and this necessitates a detailed and minute description not only of the general principles involved, but also of the art of manipulation. This is deemed necessary to promote efficiency in the work and thus reduce the time and labor required. In his book on "Shop Management", Mr. Frederick W. Taylor gives a minute description of the most simple work of handling pig iron which, to most people, would seem to need no explanation. As it is acknowledged that secondary stresses require an enormous amount of time, any seemingly unnecessary yet important explanation would not be out of place in presenting a method that is considered perfectly new.

With reference to the writer's graphic method it is indeed gratifying to know that the author found it to give results that are "surprisingly accurate". This is in agreement with what the writer himself proved when testing the method and later with the results obtained by his students at the Tangshan Engineering College. The author, however, expressed his unwillingness to recommend the method on the basis that all graphic methods are undesirable; his objections therefore will virtually exclude every graphic solution from practical use. First, he seemed to dislike the use of a large-sized drawing paper on the ground that it might become unwieldy. It is true that to solve accurately a long-span truss under unsymmetrical loading a sheet of unusually large size is indispensable; but this is not a feature peculiar to the writer's

method alone—all graphic methods, without exception, are subject to this disadvantage. When a large-sized drawing paper is compared with ten or more pages of tabulated computations as used in other methods (the author used seven tables in the Manderla-Gauss method, requiring fully ten sheets of 8 by 12-in. paper), it is only a question of individual taste as to which is more adaptable to use. Personally, the writer much prefers the drawing to the tabulated sheets for the evident reason that it conveys a complete mental picture of the problem and thus enables the computer to see the effect of one stress on the other. This is important from the standpoint of design, as it will help to change the proportioning of the members so as to arrive at a more balanced design. When the designer is faced with a large mass of numbers, whether tabulated or not, he is really solving a mathematical problem and is at a loss to realize the significance of the result obtained in every step of the procedure. Inasmuch as secondary stresses are important on account of their practical bearing on the design, rather than of their mere mathematical interest, every method proposed for their solution should take this factor of illustration into account.

The author further objects to the graphic method because of the difficulty of adapting it to trusses with subdivided panels. This is true for the method presented in the author's form, but the writer believes that it can be modified to accomplish the purpose, as it is certainly susceptible to improvements.

It is rather surprising that the author complains of the labor required to arrive at the "base" and "vertex" lines as "excessive". He did not give the actual time consumed in getting these sets of lines; the writer, from personal experience in solving for a number of trusses, did not find it unbearable. To construct those two sets of lines would require some time, but it must be remembered that this corresponds to the time required to form and solve the large set of simultaneous equations demanded by other methods like those of Manderla or Mohr. To determine whether or not the time or labor required is excessive, an accurate record of the actual time consumed for each method should have been kept, thus rendering possible a conclusive comparison. The writer hopes that the author has made such a record in his work, as the time element is an important factor in the discussion of methods proposed for the analysis of secondary stresses.

In connection with the "base" and "vertex" lines, the author remarks that because of the many repetitions of the same process, the labor involved "is bound to become extremely monotonous". In the writer's opinion, however, this feature of the method is something that deserves merit instead of criticism, as it is well known that to cultivate speed and accuracy "repetition of the same process" is highly desirable. It must be remembered that the subject of secondary stresses is important because of its practical bearing on the design; if it appealed only to the mathematician it would not have interested the bridge engineer. Most bridge engineers object to the consideration of secondary stresses largely because of the excessive labor required for their complete solution. Any means proposed to facilitate the solution is, therefore, in urgent demand. Such psychological effect as monotony, even if it may

exist and be unpleasant, is indeed too trivial to mention if the method be adaptable to practical use.

The author seems to judge the writer's graphic method from his experience with other graphic solutions, for in discussing the question of checking devices, he states that "any graphical method is objectionable in the drafting-room as a complete and thorough check by a second man requires an entirely new solution of the whole problem." It is true that if the second man's check is to make sure that every line in the drawing has its correct position, he will have to repeat exactly the same process as performed in the first solution; but if his purpose is to determine the correctness of the result, there are in the writer's method two neat and simple checks. In the first place (Fig. 57), there are two sets of "base" and "vertex" lines for the first triangle of the truss (Triangle A) each using one end of the hip vertical as the vertex. This gives the lines as marked "Triangle A, Vertex (2)" and "Triangle A, Vertex (3)." Now only one of these two sets is required in the solution of the problem while the other is not used until all the "correct deformation contours, r," are found. If the contours for the vertices of the first triangle satisfy the other set of base and vertex lines, not used in the solution, the correctness of every step in the procedure is thereby insured. (This is similar, in a way, to the check of an ordinary Maxwell stress diagram.) Another check of the solution is obtained by drawing equilibrium polygons around every joint of the truss. If the secondary stresses produce no moment around the joints, the correctness of the secondary stresses themselves is also proved (or the writer's graphic method of successive deduction may be used instead). It is evident, therefore, that the writer's graphic method is self-checking and there is no necessity of going over the whole process, even if it has to be checked by a second man.

The author questions the use of two 45° lines with which to close the deformation contour. Although these lines are not essential to the solution of the problem, they are introduced for the purpose of furnishing an additional check, as their intersection point must lie on the deformation line constructed for the outside angle of the truss around the joint.

The value of the writer's graphic method will be greatly enhanced by using a drafting machine. The time saved may be compared with that in the analytic solution by using an adding machine.

The writer's analytic method was evolved for a twofold purpose: First, to afford a practical solution of the problem, reducing much of the labor and time required in comparison with the existing methods; second, to introduce a new arrangement of computation believed to be more rational and useful than the ordinary tabulated form. The principles involved in this analytic method are simple and are believed to be more understandable than most of the existing methods. Were it not for the fact that a novel form of computation has been evolved at the same time, intended to promote efficiency and reduce the chances of making mistakes, the description of the method would have been materially shortened.

The writer is much disappointed that the author has failed to mention some of the exclusive features of the analytic method, especially in regard to the amount of time required for a solution. The writer has found from repeated

experience that under symmetrical loading the analytic method would require not more than one-half the time necessary in other solutions, whether the span is long or short. As full loading is probably the only type that will be investigated for secondary stresses in practice, in view of the fact that those stresses are now rarely investigated for any kind of loading, the writer's analytic method would supply a practical working tool for the modern bridge office. It is more rational and systematic than the others and requires only a few hours' work for a complete solution. When the bridge office has to design a large number of standard trusses the writer's method is even more useful, on account of the fact that the "computation diagrams" may then be blueprinted for permanent use.

Under unsymmetrical loading the author finds that the coefficients of the unknowns increase very rapidly as triangle is added to triangle. The writer is not unaware of this shortcoming of the method, as he has also tested the method for unsymmetrical loading, but on a closer study of the various elements involved, he does not consider it to be very serious. The reason why those coefficients seem to follow on an ever-increasing trend, is due to the peculiar way in which they are formed. Almost all the coefficients in the U-tables are obtained by adding numbers derived from the previous coefficients. The major part of the arithmetic operations required, therefore, is addition, which is the easiest form of calculation even with large numbers. Subtraction of numbers is found in rare cases, while multiplication and division are necessary only in the moment equations around the joints and the checking equations in each triangle. With most of the arithmetic operations in addition, the writer cannot see that the practical value of the analytic method would be materially reduced even in a long-span truss.

The analytic method has a unique check which must be satisfied as soon as the stresses in a triangle are completely known; but, as the writer noted in the printed abstract of his thesis, "particular attention should be paid to the solution of equilibrium equations and also to the correct substitution of the values of U, as the checking equation does not apply in either case." In criticizing the checking feature of the analytic method, the author has probably overlooked that statement.

To those who are familiar with the writer's paper, it is probably not necessary to remark that the analytic method is also adaptable to trusses with subdivided panels. Whether the triangles of the truss have vertices in the interior or on the boundary of the frame, does not seem to have any effect on the utility of the method. A fair comparison can be made only by applying all methods to the same kind of structure.

It will be noted that in the analytic method the computations are arranged so that every operation has a predetermined order and all necessary calculations are clearly shown in the diagram, thus eliminating the personal equation and facilitating a thorough check at any future time. Another exclusive feature of the method is found in the fact that the unknowns of the problem are reduced to the secondary stresses themselves, which enables the computer to obtain some idea of their relative importance as soon as they are found. It is

sincerely hoped that these features may provoke new ideas in the subsequent investigations of secondary stresses.

In 1922, two of the writer's students at the Tangshan Engineering College, Messrs. T. S. Yen and T. H. Kê, applied his process in a general way to Mohr's method, thereby arriving at two modified forms, graphic and analytic, which enabled them to solve the problem in much less time than with the original method. These modified forms were patterned very much after the writer's methods except that the angular rotation of the joints were used as unknowns instead of the deformation contours. This shows that a continued interest in this subject will broaden the scope for investigation and any step tending to promote the interest cannot be taken in vain.

The writer wishes to express his indebtedness to the Society for the publication of this valuable paper of Dr. von Abo, especially as nearly one-quarter of the printed matter is devoted to the writer's two methods. This worthy task undertaken by the Society will surely be deeply appreciated by the Engineering Profession at large.

Edward Godfrey,* M. Am. Soc. C. E. (by letter).—In discussing the subject of secondary stresses of course the first thing to establish is a definition of the term. There is a sharp difference of opinion as to the importance of secondary stresses, and little can be accomplished in analyzing this difference of opinion unless the term "secondary stress" is first defined and understood.

Engineering terms must be defined by engineers. The dictionary is of little or no use except to give the general meanings of the words. The engineering application of these words is a matter for engineers to agree upon or to develop by custom and usage, guided somewhat by authoritative utterances. Many engineering terms are not found in the dictionary, although they are in common use among engineers and have definite meaning.

In general, primary stresses are well understood. They include axial tension or compression in members ordinarily designed for such stresses. They include bending in any member subject to transverse loading, whether this loading be an extraneous load or the weight of the member itself. In other words, a compression or tension member, as the chord of a truss which carries floor ties, is not subject to secondary stress by reason of this transverse loading, for both the direct axial load and the transverse load are of primary importance in the design of these members. In the same manner, a long horizontal member must be designed to carry its own weight, as a primary consideration, and it is only when custom and experience have proven that members are so short as to give bending stresses, due to their own weight, of no consequence in the design, that these stresses may be neglected.

Stresses that are produced by wind loads, whether direct axial stresses in truss members or bending stresses created in these members by wind shears that must be carried by the truss members to an adequate resisting medium, are not secondary. They are primary, and when of considerable magnitude must be accounted for in the design. Only when they are small in comparison

* Structural Engr., Pittsburgh, Pa.

with the main truss stresses or floor system stresses is there any warrant for neglecting them.

Stresses that are produced by an eccentric application of the direct load of a tension or compression member are not secondary. Specifications require that axial stresses be applied at the center of gravity of the cross-section of a member and imply or express the requirement that if axial stresses are not so applied, the bending moments produced must be provided for.

When a girder or beam rests on a bracket on a column without web connection and without connection of both flanges to the column, there is a definitely calculable bending moment in the column due to this bracket load, and the column must take all this bending moment—the girder or beam cannot take any part of it. The bending moment is not a secondary stress in the column. It is conceivable that such a load could wreck the column, the stress being greater in amount than the direct axial load on the column.

In all the foregoing cases there can be no dispute, in proper designing, as to whether and when the stresses referred to should be accounted as worthy of consideration. When by ordinary calculation these additional stresses amount to a considerable fraction of the axial stresses, they must be governing factors in proportioning the members. Safety in structures demands this.

Some of the cases that will doubtless be conceded by all to be classed as secondary stresses are the following:

(*a*) In a column to which a girder is rigidly attached—the bending stresses due to the deflection of the girder. It is assumed that the plane of the web of the girder coincides with the axis of the column.

(*b*) In a truss rigidly riveted at all joints—the bending stresses due to the deflection of the truss.

(*c*) In a pin-connected truss—the bending stresses due to the tendency of the members to rotate as the truss deflects, the friction on the pins supplying the force.

All these have the common characteristic that they are almost universally ignored by designers.

In designing, a difference of opinion as to the precise use of the words "secondary stresses" is of little importance. As intimated in the beginning of this discussion, however, the sharp difference of opinion as to whether secondary stresses are worthy of consideration in design is of great importance and the line of demarcation in this difference of opinion is that outlined in the foregoing classification. It is pertinent, in considering a subject of this nature, to inquire into the basic assumptions and to establish their soundness. If extremely complex mathematics must be used in the design, it is particularly appropriate to establish the necessity for that method of design; otherwise engineering is burdened with unnecessary complications.

One of the simplest structural problems is that of designing, for a given loading, two columns and the girder connected to and supported by them. If this girder rests on brackets on the sides of the columns, with no web connection and no top flange connection, the span is the distance center to center of these brackets, and the bending moment on the column is simple to cal-

culate. This is not good construction, however, and would not ordinarily be considered good engineering, because lacking in rigidity.

Suppose, then, the girder rests across the top of the column or has a riveted web connection to the side of the column or has top and bottom flange connections to the column. Any one of these accepted and proper details of construction creates a condition that, theoretically, demands consideration of bending moments in the columns due to the deflection of the girder. The same condition theoretically would permit the design of the girder for a span less than the distance between the columns. No practical designer (that is, no person actually engaged in the practical design of structures) ever designs columns for these bending moments, nor does a practical designer who is careful ever use less than the distance center to center of the supporting posts for the span of a girder, where the posts support no other load than that transmitted by this girder.

The burden laid on the practical designer would be great if he were required to apply the method of least work in the solution of this simple problem. It would be enormous, in fact, unbearable, if he were compelled to follow this method throughout in the design of a small building.

General acceptance of a system of design has no weight if logic or tests can prove it erroneous, but logic and tests must show a pretty good case before they can displace a generally accepted standard of design.

The best tests are the practical tests of existing structures. The writer believes he can state without fear of contradiction that no steel structures have failed because the designers have neglected to take into account the secondary stresses due to deflection of the girders. He will go a step further and state that he does not believe it is possible for a structure to fail, if the ordinary rules of design are followed, from such cause as the deflection of the girders.

The argument of logic is in favor of the standard method of designing and against the ultra-theoretical. If steel were brittle and perfectly elastic, like glass, this would not be the case—all calculable stresses would have to be accounted for; but steel has a property that makes it safe for structures, the property of toughness or malleability. Theory can no more ignore this property than it can ignore any other known property of a structural material.

Consider the following two cases where the elastic theory shows exactly equal stress in the columns. Each case consists of a pair of columns and a girder supported by them. All four columns are identical in cross-section; but one girder is connected rigidly to the columns, and the other simply rests on brackets, the distance from center of column to bracket support being 3 ft.

The girders are ample in section for their loads, but the columns are weak to the extent that the unit stress, computed theoretically, is the ultimate for the columns, although the columns are capable of taking the direct stress due to the girder load. The theory by which the unit stress in the rigidly connected system is computed is that which considers relative rigidities of the columns and girders and utilizes the method of least work or some other involved process, and finds imaginary points of inflection 3 ft. from the centers

of the columns. Thus the unit stresses, theoretically, are identical when the systems are loaded.

The system in which the girder rests on the brackets will fail. The other system will not fail.

The first system will fail because there is nothing whatever in it to come to the aid of the columns when they deflect in the act of failing. The second system will not fail because the girder prevents the columns from deflecting to the point where they will crush or buckle.

These facts can be reasoned out by analysis, starting with the known properties of steel. They can be demonstrated by test. Every engineer who has examined many existing bridges is familiar with the fact that there are cases without number where the theoretical stresses, if realized, would wreck the structures in which they occur. These facts provide a sound basis for the general disregard of secondary stresses as defined in the present discussion. Unfortunately, some designers do not discriminate between computed stresses that may with impunity be ignored, and that are among those classed as secondary in this discussion, and the other stresses which are herein defined as not secondary.

What is said of the effect on a structure of secondary stresses due to the deflection of a girder is equally true of secondary stresses in truss members due to the deflection of a riveted truss or a pin-connected truss, either because of the rigid joints or because of rotation on the pins. The point of distinction between the case that needs consideration and the one that does not is the possibility of continued deflection. If a member can deflect only so far and is positively prevented from deflecting any farther, and if reverse deflection (that is, bending back and forth) is not a possibility, it is known from the properties of steel that, in general, failure is impossible.

A bar, rod, or wire can be bent over a corner or around a curve into such a shape that calculations, based on the perfect elasticity of steel, would show ultimate stresses in the piece, and yet in this shape it will carry a load practically if not fully equal to its capacity as a straight member. Has theory any right or warrant to say this member is unsafe, when countless members in this identical position are doing full service without any distress whatever? This bent member will carry the load imposed on it indefinitely—forever, in fact—barring deterioration. What standing has the theory which declares the member to be dangerously stressed?

On the other hand, if the piece were bent back and forth repeatedly, even through a much smaller angle than would be safe for the first bend, it would soon, or eventually, break. This behavior, as well as the other, can be reasoned from the known properties of steel—its toughness and malleability; and these properties are just as real and, when understood, just as dependable as the elasticity of steel, which is the only recognized property of the metal that the average theorist uses in his theorizing.

There are grades of steel, very high in carbon and very brittle, that would not stand safely even one bend that other steels would stand with perfect safety; but structures are not made of the hard, brittle grades of steel. It

is not proper to introduce into the theory of structures the properties of a steel that is not used in the fabrication of structures. Economic, safe, and proper design is not advanced thereby.

Consider the two pairs of posts in Fig. 106. The posts of one pair, *A*, have been jacked apart and a ball placed between them. The posts of the other pair, *B*, are bowed in their fabrication. All posts are of the same cross-section. The unit stress from direct load in each of the four posts is the same, namely, 10 000 lb. per sq. in. The unit stress from bending is, theoretically, exactly the same, namely, 12 000 lb.; but the bending moment in one pair is due to the wedging or springing action of the ball forced between the columns, while that in the other pair is due to the bowed shape of the columns and the eccentric application of the load.

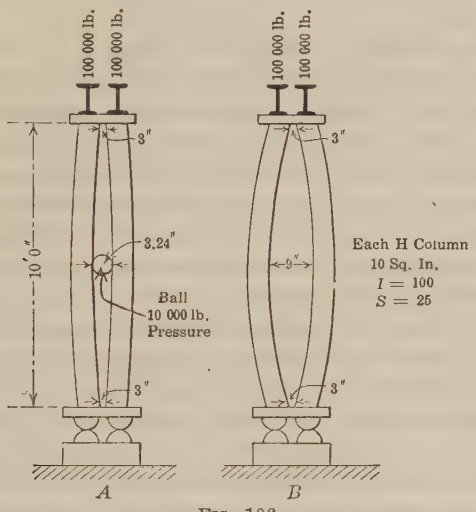

FIG. 106.

In spite of the identical stresses in these two pairs of columns, theoretically determined, they are by no means equally unsafe. The writer would not hesitate to condemn the pair of columns shown at *B*, if he found such a condition in a structure. He would not be greatly concerned for the safety of the structure, if he found the condition at *A* existing.

The condition at *B* is a menace to the integrity of the columns, and failure, once started, would continue without hindrance. Part of the deflection of 3 in. (about $\frac{1}{8}$ in.) is produced by the load which the columns are supporting. There is, therefore, the start of failure in the columns as shown. The load will not cause any deflection in the columns at *A*, but will relieve some of the pressure on the ball.

In the fabrication of "fish-belly" compression members the parts are bent cold. This puts into the metal initial stresses that correspond to, in fact, are much greater than, those found by the theorist in members of a truss as due to secondary stress. The lattice-bars in these members with bowed parts, however, hold these parts against deflection, and no weakness is developed in the

members. In exactly the same manner the theoretical unit stresses found in the members of a truss due to the secondary stress caused by deflection of the truss mean nothing, because their effect ceases at their inception and cannot be augmented. In fact, it is very doubtful if they actually exist. The tests on the Hell Gate Bridge showed far from consistent and expected results. Malleable metal, such as structural steel, can take up and absorb such stresses. They mean little or nothing as regards safety.

D. B. Steinman, M. Am. Soc. C. E., who made the tests referred to, states:* "For the highest percentages of secondary stresses, the measured values are only a small fraction of the calculated values". Again, "The actual secondary stresses will generally be lower than the calculated values. There is an automatic readjustment of strains within a structure in such direction as to relieve the secondary stresses".

Referring to measurements made on buildings it has been stated† that: "At certain points of heavy columns where one might reasonably expect considerable bending to be developed by distortion or secondary effect, there is generally speaking no bending". As a result of tests of secondary stresses, O. H. Ammann, M. Am. Soc. C. E., states:‡ "Eccentric connections increase the secondary stresses almost invariably and should therefore be avoided". Such stresses are not true secondary stresses. He also states, "Rigid riveted connections, on the other hand, always act favorably, distributing the moments and reducing the stresses from eccentric connections". It is rigid connections which, theoretically, cause the greatest secondary stresses. He states again: "The results of the investigation indicate that rigidity of members and connections tends to prevent localization of high secondary stresses and may therefore constitute an element of safety rather than of weakness".

Imperfections in workmanship can be shown theoretically to produce far greater stresses in structural members than are produced by deflections of these members in the structure. Suppose, for example, that a girder is milled out of true a small fraction of an inch. When this girder is riveted to the column, the column will be bent to a far greater extent than the deflection of the girder would bend it, yet a practical engineer, understanding the properties of steel, would not concern himself in the least if this condition were found to exist in his structure.

Again, suppose a column or truss chord were milled out of true. The calculated stress could be enormous in intensity—sufficient to break any material that is brittle like glass or concrete. In steel the member may show no distress whatever. Of course, careless workmanship is not a thing to be desired or encouraged, but any engineer who, like the writer, has examined in detail a hundred or more existing structures and observed these imperfections, and has seen metal peened down by reason of its malleability (under high stress), by stresses that, theoretically, would wreck a structure, is aware that malleability is a property of steel that can be relied upon under certain conditions.

* *Transactions*, Am. Soc. C. E., Vol. LXXXII (1918), p. 1071.
† *Engineering News-Record*, October 23, 1924, p. 655.
‡ *Loc cit.*, p. 668.

The outstanding example of a structure that has many varieties of secondary stresses due to its design—stresses of theoretically great intensity—is the Firth of Forth Bridge in Scotland, but none the less this bridge is relatively one of the safest in existence, because of its design and because of the very rigidity of the joints that gives rise to the theoretical secondary stresses.

If the theory of secondary stresses and the perfect elasticity of steel is worthy of consideration in design, there are other cases where it would have application. One of these is a simple web splice in a girder. The writer knows of an eminent engineer, now deceased, who insisted that every web splice should be proportioned for bending or flange stress as well as shear, for the reason that the bottom edge of the web plate elongates and the top edge shortens as the girder deflects. As designers know, it is customary to splice the web plate for its shear only, unless it is desired to take advantage of the aid a web plate supplies in taking up flange stress. In many girders, particularly light ones, there is no need of including the bending value of the web, and a single row of rivets on each side of the cut is sufficient for the shear. To splice the web plate for bending would require four or more vertical rows of rivets, or extra horizontal plates—an expensive detail merely to satisfy a theory; for consider what could happen if a web plate is spliced for shear only, say, with a single row of rivets on each side of the cut. Suppose the extreme rivets should slip an insignificant trifle (the stretch of the flange angle in 3 in.); this would not impair their value for taking shear one iota. With the flanges proportioned for the full flange stress, there is absolutely no weakening of any kind in the girder.

In a triple riveted splice in a boiler or tank seam (Fig. 107), if the elastic theory be applied in a manner similar to the way it is applied in computing secondary stresses, it will be seen that there cannot be equal distribution of stress among the three rivet lines. In one plate the intensity of stress is twice as great as in the other plate, where the two plates lie side by side. Ignoring malleability, this joint would not be safe, for there is no way to work out equal shear on the three rows of rivets and simultaneously equal stress on the contiguous layers of plate. Quadruple riveted joints and, in fact, almost all splices offer greater theoretical difficulties than these.

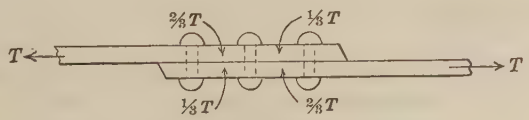

FIG. 107.

As the whole fabric of the secondary stress theory rests on the soundness of its fundamental assumptions, and as it is proven by the cases presented that these fundamental assumptions are without warrant in fact, or experience, or test, it is clear that there is no justification for consideration of secondary stresses nor for adding the complexities of that theory to the literature of engineering.

In the last few years two bascule bridges have exhibited failure in the members that supported the heavy counterweights. Statements have been

published to the effect that lack of consideration of secondary stresses in the design of these counterweight supports was responsible for the failures, and engineers who advocate the ignoring of secondary stresses are held accountable for these failures and any others of a similar character that may occur.

Little is given in the way of details of the supports of these counterweights. However, one thing is made clear, namely, that the counterweights are of concrete cast around built-up truss members. The raising and lowering of the counterweight causes these structural members to bend back and forth as one would bend a wire to break it. It is not to be expected that truss members would withstand this bending back and forth due to a heavy counterweight moving through a large angle in changing its position. If loaded bridges were to be turned upside down and all stresses and moments reversed many times a day, this feature would have to be considered in their design, just as a revolving axle must be designed with a larger factor of safety than is necessary for a stationary member in bending.

The writer has yet to find any case where secondary stress is worthy of computation and consideration in design.

Cyrus C. Fishburn,* Esq. (by letter).—In using Mohr's semi-graphical solution for the moments at the ends of the members of a truss due to the change in length of the members, the following check is useful in verifying the equations before solving for the unknowns, thus insuring against arithmetical errors in the original equations.

The Mohr semi-graphical method first requires the deflections of each member of the truss, which are obtained by means of the Williot diagram. An equation is then written for each joint of the truss, the unknowns being the rotation or angular change at the joints. These equations are derived from the basic equation:

$$M_{AB} = 2\,E\,K_{AB}\,(2\,\theta_A + \theta_B - 3\,R)$$

in which, M_{AB} is the moment at the end, A, of the member, $A\,B$, K_{AB} is equal to $\frac{I}{L}$ (movement of inertia divided by length) for the member, $A\,B$, θ_A and θ_B are the rotations at the ends, A and B, respectively, and R is equal to $\frac{d}{L}$, d being the deflection of $A\,B$. From this fundamental equation, a series of other equations is derived by equating the sum of all the moments at any joint to zero. The equation for Joint A (Fig. 108) is:

$$\begin{aligned}&[2\,\theta_A\,K_{AB} + \theta_B\,K_{AB} - 3\,(R\,K)_{AB}]\\ &+ [2\,\theta_A\,K_{AC} + \theta_C\,K_{AC} - 3\,(R\,K)_{AC}]\\ &+ [2\,\theta_A\,K_{AD} + \theta_D\,K_{AD} - 3\,(R\,K)_{AD}]\\ &+ [2\,\theta_A\,K_{AE} + \theta_E\,K_{AE} - 3\,(R\,K)_{AE}] = 0 \quad \ldots\ldots\ldots\ldots (120)\end{aligned}$$

which may be written in the form:

$$\begin{aligned}&2\,\theta_A\,(K_{AB} + K_{AC} + K_{AD} + K_{AE}) + \theta_B\,K_{AB} + \theta_C\,K_{AC} + \theta_D\,K_{AD}\\ &+ \theta_E\,K_{AE} = 3\,[(R\,K)_{AB} + (R\,K)_{AC} + (R\,K)_{AD} + (R\,K)_{AE}] \quad \ldots\ldots (121)\end{aligned}$$

* Graduate Student in Civ. Eng., Univ. of Illinois, Urbana, Ill.

It is to be noted that the left-hand member of Equation (121) contains the rotation, θ, of both ends of all members entering the joint, having as coefficients the K's of the members. The right-hand member of Equation (121) contains $3\,R\,K$ for all members.

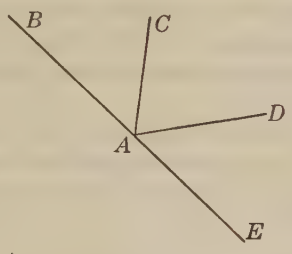

Fig. 108.

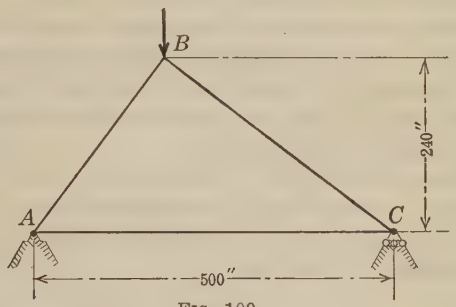

Fig. 109.

The equations for all joints in the structure of Fig. 109 are presented in tabular form in Table 36.

TABLE 36.—Functions of Joints.

	Equation.	θ_A	θ_B	θ_C	Right-hand member of equation.
Joint A	(1)	$2(K_{AB}+K_{AC})$	K_{AB}	K_{AC}	$= 3\,[(RK)_{AB}+(RK)_{AC}]$
Joint B	(2)	K_{AB}	$2(K_{AB}+K_{BC})$	K_{BC}	$= 3\,[(RK)_{AB}+(RK)_{BC}]$
Joint C	(3)	K_{AC}	K_{BC}	$2(K_{AC}+K_{BC})$	$= 3\,[(RK)_{AC}+(RK)_{BC}]$

Before setting up Equations (120) and (121), it is convenient to tabulate the geometrical properties of the members. Such a tabulation for the simple truss in Fig. 109 is presented in Table 37.

TABLE 37.—Properties of Members.

Member.	Length, L, in inches.	Area, A, in square inches.	I, in inches^4.	$K=\frac{I}{L}$.	Stress, P, in pounds.	$\frac{PL}{AE}$, in inches.	Deflection, d, in inches.	$R=\frac{d}{L}$.	$\frac{3RK}{3I}\frac{d}{L^2}$.
(1)	(2)	(3)	(4)	(5)	(6)	(7)	(8)	(9)	(10)
AB	300	32	3 000	10	− 500 000	− 0.1562	+ 0.408	+0.00136	+0.0408
BC	400	24	1 600	4	− 375 000	− 0.208	− 0.307	−0.000768	−0.009216
AC	500	20	1 500	3	+ 300 000	+ 0.250	0	0	0
Totals...	...	..	.....	17	.....	.....	.....	.....	+0.03158

It may be seen by inspection of the equations in Table 36 that the sum of the coefficients of θ in all three equations equals 6 $(K_{AB} + K_{AC} + K_{BC})$, or six times the sum of all the K's in Column (5) of Table 37. Similarly, the

sum of the right-hand members of these equations equals 6 $[(RK)_{AB} + (RK)_{AC} + (RK)_{BC}]$, or twice the algebraic sum of the quantities in Column (10) of Table 37. This check applies to any truss, irrespective of the number of joints.

The numerical value of the quantities of Table 36, are substituted from Table 37, in Table 38. The sum of the arithmetical coefficients of the θ's in Equations (1), (2) and (3) of Table 38 equals 102, or six times the total, 17, of Column (5), Table 37. Likewise, the algebraic sum of the numerical values of $3RK$ in these equations, equals twice the algebraic total, 0.03158, of Column (10), Table 37.

After checking the accuracy of the equations in the manner shown, the work of solving them simultaneously may be continually verified by the well known method of carrying a check column. Such a check column is illustrated in Table 38.

TABLE 38.—Numerical Check.

Equation.	θ_A	θ_B	θ_C	Right-hand member of equation.	Check column.
(1)	+ 26	+ 10	+ 3	+ 0.0408	+ 79.8
(2)	+ 10	+ 28	+ 4	+ 0.03158	+ 73.58
(3)	+ 3	+ 4	+ 14	— 0.00922	+ 11.78
(4)	+ 1	+ 0.385	+ 0.115	+ 0.001569	+ 3.069
(5)	+ 1	+ 2.8	+ 0.4	+ 0.003158	+ 7.358
(6)	+ 1	+ 1.333	+ 4.667	+ 0.003073	+ 3.927
(5) — (4) = (7)	.....	+ 2.415	+ 0.285	+ 0.001589	+ 4.289
(5) — (6) = (8)	.....	+ 1.467	— 4.267	+ 0.006231	+ 3.431
(7)	.....	+ 1	+ 0.116	+ 0.000658	+ 1.774
(8)	.....	+ 1	— 2.908	+ 0.00424	+ 2.337
(7) — (8) = (9)	.....	.....	+ 3.019	— 0.003582	— 0.563
			$\therefore \theta_C = -0.001187$		

The check column contains the algebraic sum of all the factors in each equation, and it is treated in the same manner as the quantities in the equations. It may be found convenient to multiply the right-hand members of the equations by a constant factor, 100 or 1 000, before adding it to the check column. The factor used in Table 38 was 1 000.

By checking the arithmetical quantities in the original equations, as written and by checking the successive steps in the solution of these equations, the chance of arithmetical error in the result is reduced to a minimum.

F. P. Shearwood,* M. Am. Soc. C. E. (by letter).—This investigation must have involved a great amount of painstaking work, and it is very useful for correctly indicating how the members of a frame will be strained under load. The labor involved in working out these stresses is immense, and it is quite impossible, under present commercial conditions, to apply it to the ordinary structure.

The real aim of designing is to produce the safest, most rigid, and lasting structure with the least amount of material. Theoretical fiber stresses should not be permitted to befog the real issue, but should be used in conjunction with

* Chf. Engr., Dominion Bridge Co., Ltd., Montreal, Que., Canada.

experience on existing structures to temper engineering judgment in designing and proportioning new structures or in determining the safety of old ones.

The term "secondary stress" is generally understood to include only those stresses which would not occur if the structure had perfectly articulated joints. This ideal condition is impossible, because of certain physical facts which cannot be eliminated; actually, secondary stresses exist in every framed structure because there is restriction to some degree in every joint.

Secondary stresses, unlike other stresses, are relieved by deformation or distortion of the material, and, provided the range of repeated deformation is not sufficient to cause fatigue, ordinary secondary stresses will not reduce the safety of the structure.

It was with great interest that the writer read Mr. Godfrey's discussion, with whom he agrees most thoroughly. Mr. Godfrey truly states that no steel structure has failed through the neglect of providing for secondary stresses. The failure of the counterweight truss members of the bascule bridges referred to by Mr. Godfrey was attributed by some to secondary stresses; but no conclusive proof of this was given. A careful study of these designs would point to an equal probability of the failures being due to the tearing effect of the embedded trusses on the main members, because the combination of concrete and embedded steel had ceased to function. The breaking of the bond of the concrete was due to the frequent reversal of the stress.

Any engineer familiar with the fabrication and erection of steelwork must realize that even in the hands of the best bridge companies, the steel is subjected to greater strains than it can ever receive under its normal loading.

It seems peculiar that, although steel is the most ductile of all materials, the design of steel structures is practically the only one in which it is customary to neglect this quality deliberately. Indeterminateness is avoided and any form of continuity is unfavorably considered, because the supports might move and cause strains beyond the elastic limit, but, in practice, many examples of steel structures are found which are safely performing their duty in spite of some injury to their members that has distorted them far beyond the ultimate strength of the material, if calculated according to the elastic theory. On the other hand, material, such as concrete, is used for all kinds of construction where continuity and other forms of indeterminateness exist in spite of the fact that these materials lack ductility.

To determine the effect of secondary stress from rigid joints on the safety of structures, it is necessary to know by experiment or practical experience whether or not restricted straining (secondary stress) really weakens members stressed in direct tension or compression in proportion to the increase of the theoretical fiber stress. Experience seems to indicate that it does not, in fact, there is much to show that secondary stress is more often a source of increased strength than of weakness.

Laurence J. Waller,* Assoc. M. Am. Soc. C. E. (by letter).—The author's work in compiling and comparing the various types of secondary

* Civ. Engr., Austin & Ashley, Los Angeles, Calif.

stress analysis has placed before the profession an invaluable compendium of scientific information.

It has seemed to the writer that, in the case of the average engineer, the selection of a method of secondary stress calculation has been almost entirely fortuitous. The sources of information are not extensive; the subject itself is not in common usage, and is relatively difficult. Faced with a choice between a number of highly technical systems and having no basis of comparison other than actual trial, engineers have largely used the system nearest at hand, with the varying degrees of labor required and accuracy attained. The author's critique makes it possible for the engineer promptly to discard complicated or inherently faulty systems in favor of the simpler and more accurate types of analysis.

The writer considers Mohr's semi-graphical method to be the most practical thus far devised for the usual type of bridge truss. The precise details of this method, however, are subject to considerable variation. Personally, the writer uses an arrangement of Mohr's method so far not touched on in this discussion, namely, that of Mr. G. A. Maney.* The nomenclature and the arrangement are lucid and concise, and possess to an eminent degree the property of being readily visualized. Contrary to the author's preference, the solution by successive substitutions will probably commend itself to the profession rather than elimination by Gauss' normal equations, particularly in the case of long span bridges. Instead of the usual substitutions, a more rapid convergence of values is effected by using in a given equation the last found values in that series. By this process, the third substitution will almost invariably give values sufficiently precise.

Extreme precision in secondary stress determination is not only unwarranted by reason of failure to secure the basic assumptions of analysis, but is also rendered futile by the modifying effect of certain factors which are not considered in the usual analyses. Under the first heading come such considerations as:

(1) The assumption of perfect fixity at the truss intersections;
(2) The assumption of perfect elastic deformation of the members between the intersections; and
(3) The assumption of constant moment of inertia.

According to the elastic theory there is bound to be considerable variation in the fixity because the moment of inertia of some gussets may be as great as that of the truss member itself, whereas the moment of inertia of other gussets may be only a small fraction of that of the main member. Indeed, German and Swiss tests, as well as tests at the University of Illinois, have indicated the lack of perfect fixity in gusset-plate connections. This lack of fixity is due to (*a*) rivet slip and (*b*) elastic deformation. The variations from the assumption of perfect fixity have been characterized† as "not introducing serious errors into the results." This finding is to be expected, but it would indicate the uselessness of highly refined secondary stress calculations.

* "Studies in Engineering No. 1," Univ. of Minnesota.
† *Bulletin No. 104*, Eng. Experiment Station, Univ. of Illinois.

Due to the variant moment of inertia and length of the gussets, there is a variant and appreciable zone of restraint past the intersections, with a resultant effect on the secondary stress.

The assumption of constant moment of inertia is, of course, never realized in practice. Deep and heavy gussets and splice members will modify materially the moment of inertia of the section and, consequently, the secondary stresses calculated on the premise mentioned.

In his discussion Mr. Steinman mentions a variation in the usual secondary stress procedure which involves the recognition of a variable moment of inertia in the members. This procedure should largely compensate for the two latter considerations.

The total stresses, primary plus secondary, as determined by the usual methods, are somewhat modified by the existence of certain concomitant conditions not usually analyzed or considered. The more obvious of these are:

(1) The effect on the unit primary axial stress of increased section due to gussets and splice members.

(2) The effect on the unit primary flexural stress of increased moment of inertia due to gussets and splice members.

(3) Faulty fabrication, including such items as incorrect rivet spacing, inaccurate facing of compression surfaces, sections that are in wind, incorrect shop lengths, etc.

(4) Initial stress in sections due to the effect of the straightening rolls.

(5) Temperature variation between different members of the truss.

(6) Eccentricity produced by flexure in the member between the panel points.

(7) Bending in the verticals caused by deflection of floor-beams.

(8) Torsion in chord members due to deflection of the floor-beams extending over part of the span.

(9) Longitudinal stress caused by friction of roller bearings at a movable reaction.

(10) Decrease in axial stress due to the fact that the floor system assumes load.

(11) Non-uniform stress intensity in outstanding legs of angles, splice members, etc.

These various factors produce stress variations which, in general, are small individually. The design should be arranged so as to correct for them as far as possible, but the calculation of their precise values is commonly disregarded by engineers. This procedure is justified by reason, for their complex nature and erratic occurrence preclude the possibility of a precise analysis without an expenditure of time out of all proportion to the small additional accuracy attained.

These considerations would indicate the futility of striving after great precision in secondary stress calculations through the medium of rigorous mathematical analyses following the so-called "precise methods". As mentioned, Mohr's semi-graphical method with the solution of equations by successive substitutions provides a lucid and expeditious analysis, and one which

possesses ample accuracy considering the modifying effect of the indeterminate factors alluded to.

Apropos of the moot questions of relative fixity of members at panel points, some recent German strain-gauge tests may be of interest.* They were taken on the center bottom chord gusset and connecting members in a truss 6.0 m. in span and 1.5 m. in height. The truss was loaded at its center upper chord panel point with a load of 50 metric tons. In every instance, a relatively close agreement was found between the actual stresses and those premised from the assumption of fixed ends. The results of this test, as of other similar tests, emphasize the statement that the fundamental theory of fixity of ends as applied to secondary stress analysis is sound; but that highly refined methods of calculation are unwarranted, because of inevitable and indeterminate modifying influences.

R. McC. Beanfield,† Assoc. M. Am. Soc. C. E. (by letter).—The author's comparative analyses of various methods and conclusions involving a graphical and analytical solution for computing secondary stresses constitute valuable additional data on a technical subject lacking in comprehensive information of a practical nature.

Most of the accepted standard methods used to compute secondary stresses involve theoretical assumptions that do not correspond to conditions in actual practice. A few of these erroneous assumptions are as follows:

1.—The use of a constant moment of inertia throughout the theoretical length of the member, whereas in most instances the moment of inertia varies greatly, particularly at the end gusset connections, which in some cases is further aggravated by the use of clip angles and filler plates.

2.—The assumption that the length of the member is the theoretical length between intersection points. The theoretical length of the member as taken between axial intersection points may become considerably shortened by the use of large gusset-plates or other end conditions. If values ranging between the theoretical length and the free length (edge of gusset-plates) are substituted in the formula, a considerable variation in results is obtained.

3.—The restraining moment at the joint: In riveted connections considerable distortion may take place by reason of the elastic deformation of gusset-plates, the initial slip and distortion of rivets, and the frictional resistance between plates, all of which make the action of the joint under load rather uncertain and produce a complex condition of stresses, wherein it is practically impossible to determine accurately the restraining moment of the joint.‡

4.—The unknown frictional resistance of pin joints: Secondary stresses for pin connections are calculated in practically the same manner as for riveted connections. If the moment at the pin joint caused by the distortion of the truss exceeds the frictional resisting moment of the pin, then intersecting members may be assumed to rotate and to offer no resistance to moment. In other words, the secondary stresses in a pin joint are measured

* *Schweizerische Bauzeitung*, September 23, 1923.

† Structural and Mech. Engr., Los Angeles, Calif.

‡ "Nickel Steel Riveted Joints," *Bulletin No. 49*, Univ. of Illinois; *Schweizerische Bauzeitung*, September 15, 1923.

by the stresses caused by the frictional resistance of the pin. Thus, the accuracy of secondary stresses for pin-connected joints depends largely on the correctness of the coefficient of friction between the pin and its bearing. There are very meager data covering the frictional resistance of pins, therefore computed secondary stresses for pin-connected joints are based on highly theoretical assumptions which may give results varying greatly from actual conditions.

The writer has had occasion to investigate the secondary stresses in a 168-ft. main balcony truss weighing approximately 250 tons, for the Shrine Auditorium at Los Angeles, Calif. A careful investigation of the secondary stresses was made because it was evident that the large, rigid, gusset connections would involve considerable restraining moments which were further complicated by reason of pin connections; some of the members had pin connections at one end and riveted connections at the other. The value of the frictional resistance between the nickel steel pins and the ordinary structural steel bearing was an unknown factor and had to be assumed.

Prior to making secondary stress computations for this truss, considerable study was given to the various accepted methods. An adaptation from Mohr's semi-graphical analytical system, as described by Mr. G. A. Maney,* was utilized and gave a clear and concise analysis, materially shorter than any of the methods suggested by the author.

The writer found some helpful data in a paper by the late F. C. Kunz, M. Am. Soc. C. E., entitled "Secondary Stresses".† Those interested in secondary stresses should read this paper carefully.

The secondary stresses in some of the members for the truss in the Shrine Auditorium were found to be too great and had to be reduced. All the secondary stresses were practically eliminated by erection methods that involved introducing initial stresses in the members by lengthening or shortening them as the deformation demanded.

In computing the secondary stresses of a number of large structural steel trusses in buildings the writer has found that the so-called approximate methods of solution, as proposed by Mohr and later suggested by Maney, give sufficiently accurate results for practical purposes and involve considerably less labor than the method proposed by the author.

In many specifications, and in some building codes, secondary stresses are not clearly defined. Some authorities allow an increase in secondary stresses ranging from 10 to 33⅓ per cent. In other words, in complicated structures in which the stresses are difficult to analyze, relatively higher unit stresses are permitted, whereas in simple frame structures which have practically no secondary stresses, a much smaller unit stress is permitted.

Little data are available relative to secondary stresses in reinforced concrete frames, particularly long span trusses. It would be interesting to know

* "Secondary Stresses and Other Problems in Rigid Frames," *Bulletin No. 1*, Univ. of Minnesota.

† *Engineering News-Record*, October 5, 1911.

what consideration was given to the secondary stresses in a number of long-span reinforced concrete trusses that have been erected.

The writer much prefers the reduction or elimination of secondary stresses in structural steel trusses by erection methods rather than by altering the design of the structure. The elimination of secondary stresses by proper erection methods does not involve complicated or expensive construction operations. As a matter of fact, the introduction of initial stresses by shortening or lengthening the members as the deformation demands and forcing them into position by jacks, or otherwise, proved to be a simple and comparatively inexpensive operation for the large balcony truss in the Shrine Auditorium in Los Angeles.

Secondary stresses should be investigated for all structural frames involving rigid or restrained joints, for even if the results may be approximate, they indicate the seriousness of neglecting them. The most efficient and economical method for reducing or eliminating secondary stresses requires considerable ingenuity on the part of the designing engineer who must be experienced and able to visualize as well as theorize.

Cecil Vivian von Abo,* Jun. Am. Soc. C. E. (by letter).—The writer is grateful to the Society for publishing his paper and to the many members who have contributed such useful information and criticism. The original idea was to investigate Dr. Mao's methods, but when the writer found them too cumbersome, he was advised by Professor Jacoby to make a thorough comparison of all existing methods. This in itself entailed a tremendous amount of work, and, therefore, he decided to confine his attention to what may be termed the more exact methods.

It was with great reluctance that, through lack of time, the writer had to forego the investigation of column action in compression members for publication in the paper, but the latter part of this discussion contains some interesting results.

Mr. Ammann raised the point that, in order to take the gusset-plates into account, each bending moment calculated on the assumption of constant moments of inertia throughout the theoretical lengths of the members should be multiplied by the ratio of its theoretical length to the clear length between gussets. On the other hand, Mr. Steinman allows for an increasing moment of inertia toward the end of each member and modifies the fundamental equations. The writer is inclined to favor Mr. Steinman's method, as it seems to be the more logical.

The writer is indebted to Professor Cain for pointing out an error in the paragraph following Equation (69). Fixing attention on the second part of Equation (69), that is, $d\,v_4 = v_4\,\psi + u_4\,\phi$ and on Fig. 21, dv_4 equals the sum of the counterclockwise moments of the ϕ's about u' plus the sum of the counterclockwise moments of the ψ's about v'. (Counterclockwise is negative in Mohr's "elastic weight" method). Not only are the axes, u, v, u', and v', turned clock-

* Care, Chf. Civ. Engr., South African Rivers and Harbors, Johannesburg, Transvaal, South Africa.

wise through 90°, but also the ϕ's and the ψ's. This gives Professor Cain's Fig. 93. Only the quantities, $(u_4 - u_1)$, $(v_4 - v_1)$, etc., remain unchanged. The first part of Equation (69), that is, $d\,u_4 = u_{4\,\psi} - v_{4\,\phi}$, interpreted by means of Fig. 93, then becomes:

$d\,u_4$ = the sum of the clockwise moments of the new ψ's about the new v'-axis — the sum of the counterclockwise moments of the new ϕ's about the new u'-axis;

that is,

$d\,u_4$ = — (the sum of the counterclockwise moments of the new ϕ's about the new u'-axis + the sum of the counterclockwise moments of the new ψ's about the new v'-axis).

This change in sign would be troublesome if open chains were to be considered, but as the theory is extended to closed chains for which both these expressions then become zero (see Equation (72)), the two parts of the equation mean one and the same thing. Any point on the closed chain is chosen as origin and any direction as that of the u-axis, which then fixes the direction of the v-axis as being at 90° clockwise to the u-axis. Equation (72), therefore, shows that the sum of the moments of the ϕ's (regarded as acting parallel to the u-axis) about the u-axis plus the sum of the moments of the ψ's (regarded as acting parallel to the v-axis) about the v-axis, is zero.

Professor Fuller calls attention to the variations of stress across a section of a member recorded by him from observations in the field. It seems desirable that a theoretical investigation should be undertaken to determine all the principal variations of stress across sections of members of an existing bridge, due to a stationary locomotive, to be followed by a practical study when the more accurate extensometers could be used. If theory and practice agree, it would go far toward proving the validity of initial assumptions. Impact investigations could then very well follow, in order to get an idea of the factor for secondary and column-action stresses. The work would be stupendous, but if the outcome was a justification for the general acceptance of higher allowable unit stresses, the saving of metal in the bridges of the future would be considerable.

Messrs. Turner and Godfrey both question the definition of "secondary stress". They have also raised some very difficult points which cannot be solved with absolute certainty mathematically. The end bending moments of a particular member are known fairly accurately and the writer demonstrates the importance to be attached to them.

It was very gratifying to note the research contributed by Dean MacKay. It is hoped that the following investigation will account for some of the discrepancies that he found in the field. It is shown, for example, that the variation in the bending moments along the length of a member is not linear. In tensile members, the bending moment curve will differ but little from a straight line, whereas in compression members it will differ widely. This would be still more marked if the unit compressive stress were increased.

Professor Beggs is to be congratulated for his laboratory studies. It would save much calculation if one could obtain a close estimate of the secondary stresses in the manner he suggests.

Professor Shedd has provided a lucid explanation of the present status of secondary stresses, and Professor Cross has given a modification of Mohr's semi-graphical method, which enhances its value. It is quite evident that a student of secondary stresses can fix his attention on the method of either Manderla or Mohr and know that he cannot do better. The writer found little to choose between them; in the light of the discussions, he would be quite prepared to give Mohr's method the premier position.

Professor Wilson has a remarkably fine method of solving the problem of cross-frames. It shows how small the range of individual research is with regard to the reading of all literature on a particular subject.

Many discussors have referred to the subject of column action and the following investigation may be of interest.

Column Action

Most of the work on the theory of column action involves complicated mathematics which makes the subject difficult to comprehend. The approximate theories are better known. They, however, are based on one of two assumptions: (1) That the ends of a column are entirely free to turn; and (2) that the ends are rigidly held. Neither assumption is true in practice. It would be interesting to consider the problem which accounts for some definite end bending moments.

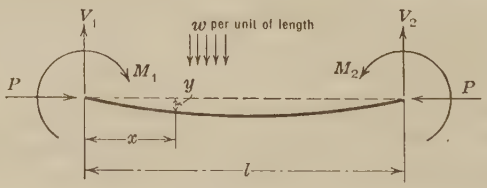

Fig. 110.

Section A

Consider a member which is subjected to an axial thrust, two end bending moments, and a uniform load over its whole length. Assume the member to be straight initially and not to be bent much at any time, so that the radius of curvature at a point will be closely given by $R = \pm \dfrac{1}{\left(\dfrac{d^2 y}{d x^2}\right)}$. Let the modulus of elasticity and the moment of inertia be denoted by E and I, and regarded as constant. Fig. 110 shows the left-hand bending moment, M_1, acting clockwise and the right-hand bending moment, M_2, acting counterclockwise.

The two end shears are given by:

$$\left.\begin{aligned} V_1 &= \frac{w\,l}{2} - \frac{M_1 - M_2}{l} \\ V_2 &= \frac{w\,l}{2} + \frac{M_1 - M_2}{l} \end{aligned}\right\} \quad \ldots\ldots\ldots\ldots\ldots\ldots (122)$$

The bending moment at the point, x, is:

$$M_x = M_1 + P\,y + V_1\,x - \frac{w\,x^2}{2} \quad \ldots\ldots\ldots\ldots\ldots (123)$$

in which, y is the downward deflection of the member at x. Therefore,

$$E\,I\,\frac{d^2\,y}{d\,x^2} = -P\,y + \frac{w\,x^2}{2} - V_1\,x - M_1$$

that is,

$$E\,I\,\frac{d^2\,y}{d\,x^2} + P\,y = \frac{w\,x^2}{2} - V_1\,x - M_1 \quad \ldots\ldots\ldots\ldots\ldots (124)$$

The general solution of the differential equation is:

$$y = A\,\sin\,Q\,x + B\,\cos\,Q\,x + \frac{w\,x^2}{2\,P} - \frac{V_1\,x}{P} - \frac{M_1}{P} - \frac{w\,E\,I}{P^2} \ldots (125)$$

in which,

$$Q = \sqrt{\frac{P}{E\,I}}.$$

Now $y = 0$ when $x = 0$ and also when $x = l$. Therefore:

$$B = \frac{w\,E\,I}{P^2} + \frac{M_1}{P}$$

and,

$$A = \frac{1}{P\,\sin\,Q\,l}\left\{\left(-\frac{w\,l^2}{2} + V_1\,l + M_1 + \frac{w\,E\,I}{P}\right) - \left(\frac{w\,E\,I}{P} + M_1\right)\cos\,Q\,l\right\}$$

$$= \frac{1}{P\,\sin\,Q\,l}\left\{\left(\frac{w\,E\,I}{P} + M_2\right) - \left(\frac{w\,E\,I}{P} + M_1\right)\cos\,Q\,l\right\}$$

using Equation (122). Hence, the solution is:

$$y = \frac{\sin\,Q\,x}{P\,\sin\,Q\,l}\left\{\left(\frac{w\,E\,I}{P} + M_2\right) - \left(\frac{w\,E\,I}{P} + M_1\right)\cos\,Q\,l\right\}$$

$$+ \frac{\cos\,Q\,x}{P}\left\{\frac{w\,E\,I}{P} + M_1\right\} + \frac{1}{P}\left(\frac{w\,x^2}{2} - V_1\,x - M_1 - \frac{w\,E\,I}{P}\right) \ldots (126)$$

Using Equation (123), the bending moment at x is:

$$M_x = \frac{\sin\,Q\,x}{\sin\,Q\,l}\left\{\left(\frac{w\,E\,I}{P} + M_2\right) - \left(\frac{w\,E\,I}{P} + M_1\right)\cos\,Q\,l\right\}$$

$$+ \left(\frac{w\,E\,I}{P} + M_1\right)\cos\,Q\,x - \frac{w\,E\,I}{P} \quad \ldots\ldots\ldots\ldots (127)$$

The maxima and minima points are given by:

$$\tan Q\,x = \frac{\left\{\left(\frac{w\,E\,I}{P} + M_2\right) - \left(\frac{w\,E\,I}{P} + M_1\right)\cos Q\,l\right\}}{\left(\frac{w\,E\,I}{P} + M_1\right)\sin Q\,l} \quad \ldots\ldots(128)$$

Consider a few typical cases, as follows:

Case 1.—Consider a horizontal strut of uniform cross-section, under a compression of P lb. and assumed to have zero end moments. This is similar to Euler's assumptions of freely hinged ends. Equation (122) becomes,

$$V_1 = V_2 = \frac{w\,l^2}{2}$$

and Equation (128) becomes,

$$\tan Q\,x = \frac{1 - \cos Q\,l}{\sin Q\,l} = \tan\frac{Q\,l}{2} \quad \ldots\ldots(129)$$

therefore,

$$Q\,x = \frac{Q\,l}{2} \pm n\,\pi,$$

in which n may be any integer. Therefore,

$$x = \frac{l}{2} \pm \frac{n\,\pi}{Q} \quad \ldots\ldots(130)$$

provided $0 < x < l$.

Equation (127) becomes,

$$M_x = \frac{w\,E\,I}{P}\left(\tan\frac{Q\,l}{2} \times \sin Q\,x + \cos Q\,x - 1\right) \quad \ldots\ldots(131)$$

As an example, take a 3 by 3 in. by $\frac{1}{2}$-in. angle-iron, with an area of cross-section of 2.70 sq. in., a least moment of inertia of 0.90 in.^{4}, and a length of 60 in., giving the ratio of l to r of somewhat more than 100. Let the strut be in the position of least strength, as shown in Fig. 111. If $Q\,l = \pi$, Equation (130) gives,

$$x = \frac{l}{2} \pm n\,l$$

and, therefore, n must be zero. For all values of Q making $Q\,l < \pi$, n will be found to be zero because Equation (130) will give,

$$x = \frac{l}{2} \pm \frac{n\,\pi\,l}{(\pi - \text{something})}$$

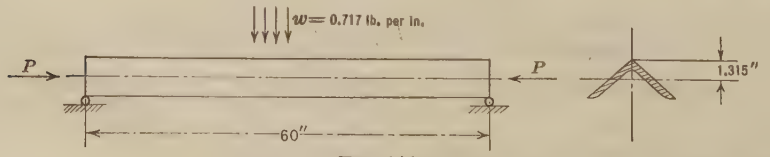

FIG. 111.

and x must lie between 0 and l. Hence, there is only one section to consider, namely the central one. $Q\,l = \pi$ was chosen both because it gives Euler's critical load and also because it is the value that makes M_x of Equation (131) infinite.

This critical load is,

$$\frac{\pi^2 E I}{l^2} = \frac{\pi^2 \times 30 \times 10^6 \times 0.90}{60 \times 60} = 74\ 022 \text{ lb.}$$

taking $E = 30 \times 10^6$ lb. per sq. in.

Study the effect of various loads less than the critical: Starting with 50 000 lb., Equation (131) gives:

$$M_{\frac{l}{2}} = \frac{w E I}{P}\left(\tan \frac{Q l}{2} \cdot \sin \frac{Q l}{2} + \cos \frac{Q l}{2} - 1\right) = \frac{w E I}{P}\left(\sec \frac{Q l}{2} - 1\right)$$

$$Q = \sqrt{\frac{5 \times 10^4}{27 \times 10^6}}; \quad \frac{Q l}{2} = \sqrt{\frac{5}{3}} \text{ radians} = 73° 58';$$

$$\frac{w E I}{P} = \frac{717 \times 27 \times 10^6}{5 \times 10^4} = 387.18.$$

Therefore,

$$M_{\frac{l}{2}} = 387.18\ (3.6206 - 1) = 1\ 014.65 \text{ in-lb.}$$

Similarly, the results for loads of 55 000 lb., etc., are given in Table 39 and Fig. 112.

TABLE 39.

Total load, in pounds.	Primary stress, in pounds per square inch.	Maximum bending moment (at center), in inch-pounds.	Secondary stress (top fiber), in pounds per square inch.	Total stress (top fiber), in pounds per square inch.
50 000	18 520	1 015	1 480	20 000
55 000	20 370	1 285	1 880	22 250
60 000	22 220	1 747	2 550	24 470
65 000	24 070	2 719	3 970	28 040
70 000	25 930	6 106	8 920	34 850
72 500	26 850	16 125	23 560	50 410
74 022	27 420	.....	.....	.....

Case 2.—Suppose two end bending moments are introduced into the foregoing problem, both assisting the weight of the beam. Take $M_1 = +\ 1\ 000$ in-lb. and $M_2 = +\ 2\ 000$ in-lb. Assuming a load of 50 000 lb., Equation (128) gives:

$$\tan\left(\frac{\sqrt{5}}{30\sqrt{3}} x\right)^c = \frac{2387.18 - 1387.18 \cos\left(\frac{2\sqrt{5}}{\sqrt{3}}\right)}{1387.18 \sin\left(\frac{2\sqrt{5}}{\sqrt{3}}\right)}$$

$$= \frac{2387.18 - 1387.18 \cos 147° 56'}{1387.18 \sin 147° 56'} = \frac{2387.18 + 1175.54}{736.46} = \tan 78.3207°$$

Therefore,

$$x = \frac{78.3207\ \pi}{180} \times \frac{30\sqrt{3}}{\sqrt{5}} = 31.765 \text{ in.}$$

and,

$$M_{\max.} = M_{31.765\text{ in.}} = \frac{2387.18 - 1387.18 \cos 147° 56'}{\sin 147° 56'} \times \sin 78° 19'$$

$$+ 1387.18 \cos 78° 19' - 387.18 = 6571.6 + 280.9 - 387.18 = 6465.3 \text{ in-lb.}$$

Similarly, the results for loads of 55 000 lb., etc., are given in Table 40 and Fig. 113.

TABLE 40.

Total load, in pounds.	Primary stress, in pounds per square inch.	Maximum bending moments, in inch-pounds.	Distance from left-hand end, in inches.	Secondary stress (top fiber), in pounds per square inch.	Total stress (top fiber), in pounds per square inch.
50 000	18 520	6 465	31 765	9 450	27 970
55 000	20 370	8 276	31 317	12 090	32 460
60 000	22 220	11 382	30 920	16 630	38 850
65 000	24 070	17 930	30 562	26 200	50 270
70 000	25 930	40 790	30 239	59 600	85 530

Case 3.—Assume two end bending moments, both in opposition to the dead weight, namely, $M_1 = -1\,000$ in-lb. and $M_2 = -2\,000$ in-lb. Considering a load of 50 000 lb., Equation (128) gives,

$$\tan\left(\frac{\sqrt{5}}{30\sqrt{3}}x\right)^c = \frac{-1612.82 + 612.82 \cos 147° 56'}{-612.82 \sin 147° 56'} = \frac{2132.14}{325.25} = \tan 81.324°.$$

Therefore,

$$x = \frac{81.324\,\pi}{180} \times \frac{30\sqrt{3}}{\sqrt{5}} = 32.983 \text{ in.}$$

and,

$$M_{\max.} = M_{32.983\text{ in.}} = -\frac{2132.14}{\sin 147° 56'} \times \sin 81° 19' - 612.82 \cos 81° 19' - 387.18$$

$$= -4449.7 \text{ in-lb.}$$

The negative bending moments mean that the top fibers have their primary stress (compressive in nature) decreased, and the bottom fibers have their primary stress increased. The results are given in Table 41 and Fig. 114.

TABLE 41.

Total load, in pounds.	Primary stress, in pounds per square inch.	Maximum bending moment, in inch-pounds.	Distance from left-hand end, in inches.	Secondary stress (bottom fiber), in pounds per square inch.	Total stress, (bottom fiber), in pounds per square inch.
50 000	18 520	— 4 449.7	32.98	3 985	22 505
55 000	20 370	— 5 715.6	32.33	5 120	25 490
60 000	22 220	— 7 893.4	31.05	7 070	29 290
65 000	24 070	—12 492	30.84	11 190	35 260
70 000	25 930	—28 573	30.35	25 590	51 520

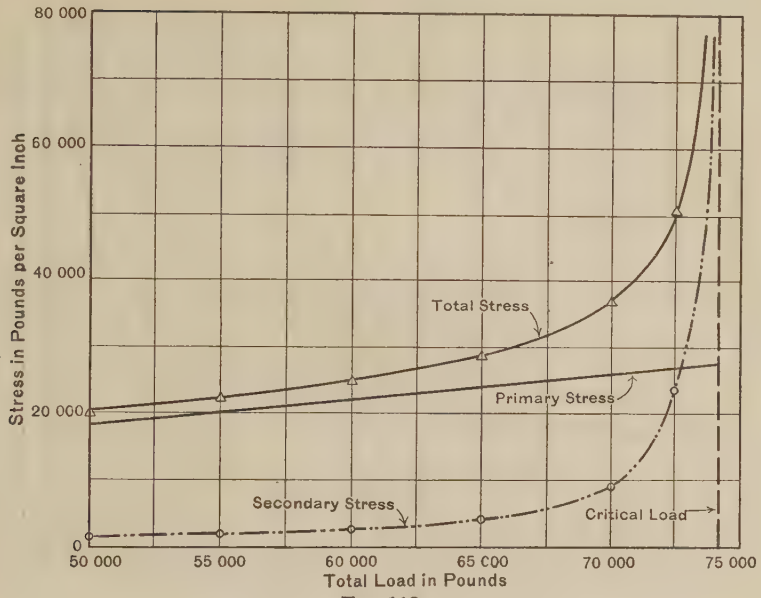

FIG. 112.

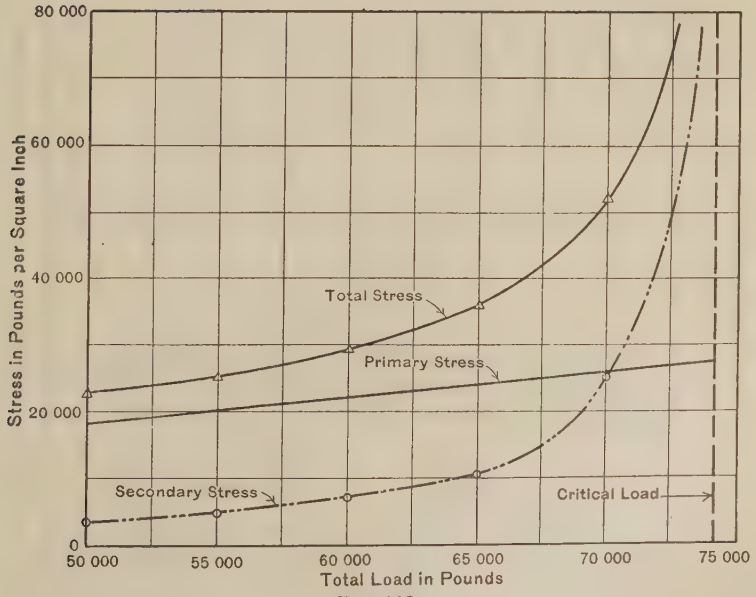

FIG. 113.

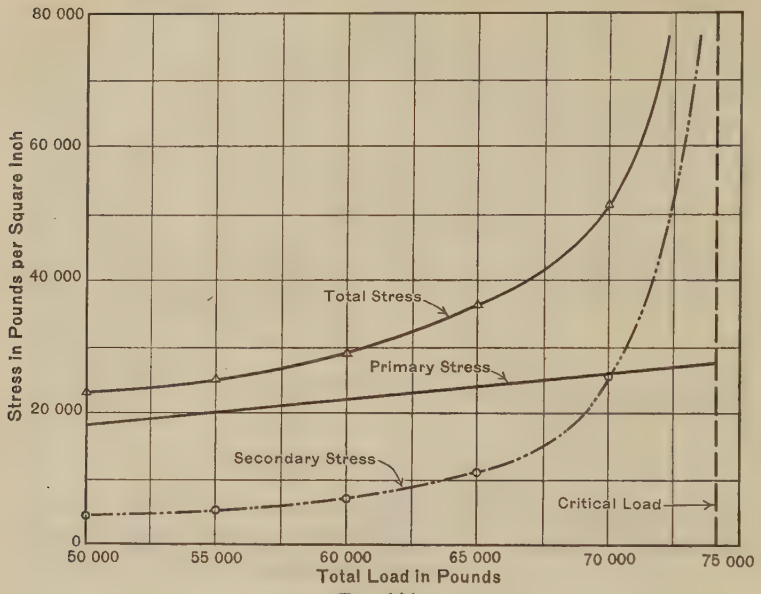

FIG. 114.

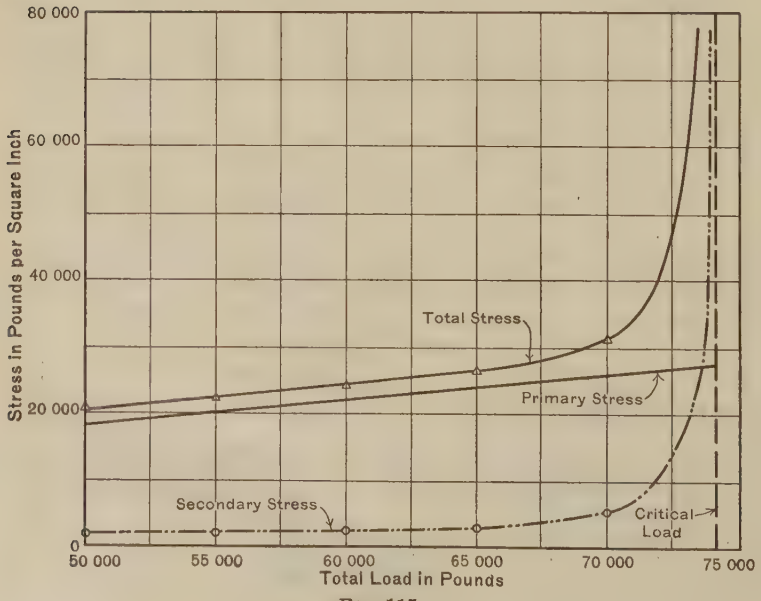

FIG. 115.

Case 4.—Consider the effect of end bending moments, opposite in character, say, $M_1 = +\ 1\,000$ in-lb. and $M_2 = -\ 2\,000$ in-lb. Considering a load of 50 000 lb., Equation (128) gives,

$$\tan\left(\frac{\sqrt{5}}{30\sqrt{3}}x\right) = \frac{(387.18 - 2\,000) - (387.18 + 1\,000)\cos 147° 56'}{1\,387.18 \sin 147° 56'}$$

$$= -\frac{437.28}{736.46}$$

giving,

$$\frac{\sqrt{5}\,x}{30\sqrt{3}} = -\frac{30.7}{180}\pi + \pi,$$

because, if anything, x must be positive. This gives $x = 60.553$ in., an amount greater than the length of the member. Hence, up to a load of a little more than 50 000 lb., the maximum bending moment occurs at one end. In this case it is — 2 000 in-lb. The bending moment at the center is:

$$M_{30} = -\frac{437.28 \sin 73° 58'}{\sin 147° 56'} + 1\,387.18 \cos 73° 58' - 387.18 = -795.66 \text{ in-lb.}$$

Considering a load of 55 000 lb., Equation (128) gives:

$$\tan\left(\frac{\sqrt{11}}{30\sqrt{6}}x\right) = \frac{(351.98 - 2\,000) - (351.98 + 1\,000)\cos 155° 10'}{1\,351.98 \sin 155° 10'}$$

$$= -\frac{421.04}{567.80} = \tan(-36° 33') = \tan 143° 27'$$

giving,

$$x = 55.470 \text{ in.}$$

The increase from 50 000 to 55 000 lb. has caused a bending moment within the length of the member, the amount of which will be numerically greater than M_2:

$$M_{55.470\text{ in.}} = -\frac{421.04 \sin 143° 27'}{\sin 155° 10'} + 1\,351.98 \cos 143° 27' - 351.98$$

$$= -2\,035.04 \text{ in-lb.}$$

Similarly, for 60 000 lb., etc., the results are given in Table 42 and Fig. 115.

TABLE 42.

Total load, in pounds.	Primary stress, in pounds per square inch.	Maximum bending moment, in inch-pounds.	Distance from left-hand end, in inches.	Secondary stress (bottom fiber), in pounds per square inch.	Total stress (bottom fiber), in pounds per square inch.
50 000	18 520	—2 000	60	1 790	20 310
55 000	20 370	—2 035	55.47	1 820	22 190
60 000	22 220	—2 220	49.68	2 000	24 220
65 000	24 070	—2 840	42.93	2 540	26 610
70 000	25 930	—5 808	35.42	5 200	31 130

It is evident that the secondary stress is reduced if there are end bending moments that produce contraflexure, and it will be still further reduced if the larger bending moment opposes the effect of the transverse load. The

analysis is also interesting in that it determines the axial load that must be subjected before bending moments larger than the end moments occur.

Case 5.—To illustrate the effect of changing the length of a compression member without changing the thrust, assume a built-up beam to be placed horizontally in a testing machine in the position of least strength, as shown on Fig. 116. Consider lengths of 120, 160, and 200 in., giving the ratios of l to r of 75, 100, and 120, respectively. As there will be some resisting moments

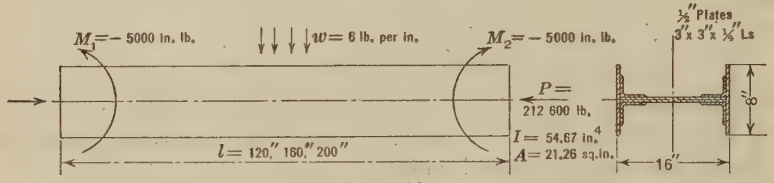

FIG. 116.

at the ends, assume them to be 5 000 in-lb. each. Up to the critical load, the maximum bending moment will occur at the center of the beam. Loads greater than the critical value are not considered. A thrust giving a primary stress of 10 000 lb. per sq. in., is applied to the three lengths, and the problem is repeated for a thrust giving a primary stress of 20 000 lb. per sq. in. Table 43 gives the results, obtained by means of Equation (127).

TABLE 43.

Primary stress, in pounds per square inch.	Length of member, in inches.	Bending moment, at center, in inch-pounds.	Maximum compressive fiber stress, in pounds per square inch.
10 000	120	6 503	10 465
10 000	160	21 052	11 540
10 000	200	52 264	13 825
20 000	120	26 364	21 930
20 000	160	77 764	25 690
20 000	200	Load greater than critical load.	

Section B.—Uniform Transverse Load Over Part of Span

Consider the problem of a compression member with an axial load, two end bending moments, and a uniform transverse load over part of the span, all acting in one plane, as shown in Fig. 117.

For $0 < x < a$,

$$M_x = M_1 + V_1 x + P y \ldots\ldots\ldots\ldots\ldots (132)$$

for $a < x < (a + b)$,

$$M_x = M_1 + V_1 x - \frac{w (x - a)^2}{2} + P y \ldots\ldots\ldots\ldots (133)$$

and for $(a + b) < x < l$,

$$M_x = M_1 + V_1 x - w b \left(x - a - \frac{b}{2}\right) + P y \ldots\ldots\ldots (134)$$

$$\left.\begin{aligned} V_1 &= \frac{w\,b\left(c+\frac{b}{2}\right)}{l} - \frac{M_1 - M_2}{l} \\ V_2 &= \frac{w\,b\left(a+\frac{b}{2}\right)}{l} + \frac{M_1 - M_2}{l} \end{aligned}\right\} \quad \ldots\ldots\ldots\ldots (135)$$

The differential equations are:

For $0 < x < a$,

$$E\,I\frac{d^2y}{dx^2} + P\,y = -V_1\,x - M_1 \quad \ldots\ldots\ldots\ldots (136)$$

for $a < x < (a+b)$,

$$E\,I\frac{d^2y}{dx^2} + P\,y = \frac{w\,x^2}{2} - (V_1 + w\,a)\,x - \left(M_1 - \frac{w\,a^2}{2}\right) \ldots\ldots (137)$$

and for $(a+b) < x < l$,

$$E\,I\frac{d^2y}{dx^2} + P\,y = -(V_1 - w\,b)\,x - \left\{M_1 + w\,b\left(a+\frac{b}{2}\right)\right\} \ldots (138)$$

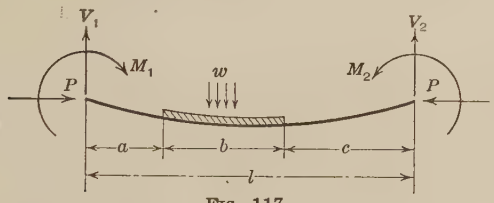

FIG. 117.

The general solutions are:

For $0 < x < a$,

$$y = A\sin Q\,x + B\cos Q\,x - \frac{V_1\,x}{P} - \frac{M_1}{P} \quad \ldots\ldots\ldots\ldots (139)$$

for $a < x < (a+b)$,

$$y = C\sin Q\,x + D\cos Q\,x + \frac{w\,x^2}{2\,P} - \frac{(V_1 + w\,a)\,x}{P} - \frac{\left(M_1 - \frac{w\,a^2}{2}\right)}{P} \ldots (140)$$

and for $(a+b) < x < l$,

$$y = E\sin Q\,x + F\cos Q\,x - \frac{(V_1 - w\,b)\,x}{P} - \frac{\left\{M_1 + w\,b\left(a+\frac{b}{2}\right)\right\}}{P} \quad \ldots\ldots\ldots\ldots (141)$$

From the six conditions: — y from Equation (139) $= 0$, $x = 0$; y from Equation (139) $= y$ from Equation (140), $x = a$; $\frac{dy}{dx}$ from Equation (139), $= \frac{dy}{dx}$ from Equation (140), $x = a$; y from Equation (140) $= y$ from Equation

(141), $x = a + b$; $\frac{dy}{dx}$ from Equation (140) $= \frac{dy}{dx}$ from Equation (141), $x = a + b$; y from Equation (141) $= 0$, $x = l$; the six constants are determined. The final equations for the bending moments are:

For $0 < x < a$,

$$M_x = \frac{\sin Q x}{\sin Q l}\left[\frac{w E I}{P}\left\{\cos Q c - \cos Q (b + c)\right\} - M_1 \cos Q l + M_2\right] + M \cos Q x \quad \ldots\ldots(142)$$

for $a < x < a + b$,

$$M_x = \frac{\sin Q x}{\sin Q l}\left[\frac{w E I}{P}\left\{\cos Q c - \cos Q a \,.\, \cos Q l\right\} - M_1 \cos Q l + M_2\right] + \left[M_1 + \frac{w E I}{P} \cos Q a\right] \cos Q x - \frac{w E I}{P} \quad \ldots\ldots(143)$$

and for $a + b < x < l$,

$$M_x = \frac{\sin Q x}{\sin Q l}\left[\frac{w E I}{P} \cos Q l \left\{\cos Q (a + b) - \cos Q a\right\} - M_1 \cos Q l + M_2\right] + \left[M_1 - \frac{w E I}{P}\left\{\cos Q (a + b) - \cos Q a\right\}\right] \cos Q x \quad \ldots\ldots(144)$$

Section C.—Concentrated Transverse Load

Mathematically, a concentrated load is considered to act at a point. If the problem of a concentrated transverse load is investigated, one arrives at a point of discontinuity for the bending moment just under the load. In practice, however, a concentrated load is always found to be spread over some definite distance. Equations (142), (143), and (144) are then used to determine the bending moments. A problem similar to the one given by Mr. Godfrey will be considered. The reference is to his Fig. 106 (*A*). By virtue of the fact that the post was initially straight at the top, the forcing of a ball between the two parts of the post will create a large bending moment at the top, and this bending moment will act in opposition to the pressure of the ball. A certain bending moment will be found at the base as well, due to friction, etc. This, too, will oppose the action of the ball.

Consider a built-up strut, held in a vertical position, with a load of 263 000 lb. on it and a horizontal pressure of 10 000 lb. at its center, acting in the direction of least strength of the strut and assumed to be acting over a space of 4 in. Fig. 118 shows the strut in a horizontal position.

Let,

$I = 106.93$ in.^{4};

Area $= 26.3$ sq. in.;

$w = 2\,500$ lb. per in.;

$$\frac{P}{E I} = Q^2 = \frac{263\,000}{30 \times 10^6 \times 106.93};$$

$Q l = 62° 15'$;

$Q c = Q a = 30° 5'$;

$Q (a + b) = Q (b + c) = 32° 10'$

Substituting in Equations (142) and (144) and differentiating, no maxima points are found within Spaces *a* and *c*, but Equation (143) gives $Q\,x = 31°\ 16'$ for the point of maximum bending moment. The center of the strut is given by $Q\,x = 31°\ 7\frac{1}{2}'$, so the maximum bending moment occurs just beyond the center.

$$\frac{w\,E\,I}{P} = 3.049335 \times 10^7$$

$$M_{max.} = \frac{\sin 31°\ 16'}{\sin 62°\ 15'}\left[3.049335 \times 10^7 \times \cos 30°\ 5'\ (1 - \cos 62°\ 15') + 10^5 \cos 62°\ 15' - 2 \times 10^4\right] + \left[3.049335 \times 10^7 \times \cos 30°\ 5' - 10^5\right]$$

$$\cos 31°\ 16' - 30\ 493\ 350 = 259\ 700 \text{ in-lb.}$$

$M_{60\ in.} = 259\ 600$ in-lb.

$M_{58\ in.} = 253\ 050$ in-lb.

Upon solving the problem under the supposition of freely-hinged ends:

$$M_{max.} = M_{center} = 295\ 900 \text{ in-lb.}$$

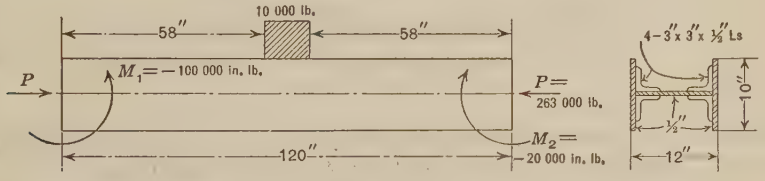

FIG. 118.

Section D.—Strut, Originally Straight, Subjected to an Eccentric Load

If *P* of Fig. 110 is off center, a positive distance, *e*, Equation (123) becomes:

$$M_x = M_1 + P\,(e + y) + V_1\,x - \frac{w\,x^2}{2},$$

resulting in changes of M_1 to $M_1 + Pe$ and M_2 to $M_2 + Pe$ in Equation (127). Hence, for eccentric loading,

$$M_x = \frac{\sin Q\,x}{\sin Q\,l}\left[\left(\frac{w\,E\,I}{P} + M_2 + P\,e\right) - \left(\frac{w\,E\,I}{P} + M_1 + P\,e\right)\cos Q\,l\right] + \left(\frac{w\,E\,I}{P} + M_1 + P\,e\right)\cos Q\,x - \frac{w\,E\,I}{P} \quad \ldots\ldots (145)$$

Similar changes occur in the Equations (142), (143), and (144).

Section E.—Tension Members

Consider the case of a tension member subjected to transverse loading, that is, assume *P* of Fig. 110 to act in the opposite direction. Equation (123) becomes:

$$M_x = M_1 + V_1\,x - P\,y - \frac{w\,x^2}{2} \quad \ldots\ldots (146)$$

Equation (124) becomes:

$$E\,I\,\frac{d^2\,y}{d\,x^2} - P\,y = \frac{w\,x^2}{2} - V_1\,x - M_1 \quad \ldots\ldots (147)$$

the general solution of which is:

$$y = A\,e^{Qx} + B\,e^{-Qx} - \frac{w\,x^2}{2\,P} + \frac{V_1\,x}{P} - \frac{w\,E\,I}{P^2} + \frac{M_1}{P} \ldots\ldots (148)$$

$y = 0$ when $x = 0$, and $x = l$ gives:

$$A = \frac{\left(\frac{w\,E\,I}{P^2} - \frac{M_2}{P}\right) - \left(\frac{w\,E\,I}{P^2} - \frac{M_1}{P}\right) e^{-Ql}}{(e^{Ql} - e^{-Ql})}$$

and,

$$B = \frac{\left(\frac{w\,E\,I}{P^2} - \frac{M_1}{P}\right) e^{Ql} - \left(\frac{w\,E\,I}{P^2} - \frac{M_2}{P}\right)}{(e^{Ql} - e^{-Ql})}$$

The equation for the bending moment at x is:

$$M_x = \frac{w\,E\,I}{P} - \frac{\left(\frac{w\,E\,I}{P} - M_2\right) - \left(\frac{w\,E\,I}{P} - M_1\right) e^{-Ql}}{(e^{Ql} - e^{-Ql})} \times e^{Qx}$$
$$- \frac{\left(\frac{w\,E\,I}{P} - M_1\right) e^{Ql} - \left(\frac{w\,E\,I}{P} - M_2\right)}{(e^{Ql} - e^{-Ql})} \times e^{-Qx} \ldots\ldots (149)$$

Section F.—Compression Members, Subjected to Pairs of End Bending Moments in Planes at Right Angles to Each Other.

This case is perhaps the most important. In considering the top chord of a bridge, end bending moments are found that act in a perpendicular plane and are due to the rigidity of the truss, and also those in the horizontal plane due to the rigidity of the lateral system. The resultant of the pair at one end is inclined at some angle to the vertical plane. If the resultant of the pair at the other end, the resultant of the uniform dead weight of the member, and the uniform wind load were to act in the same inclined plane, one would perhaps be justified in applying the theory of unsymmetrical bending.* This supposition is hardly ever true. It seems, however, that if the forces and moments in the vertical and horizontal planes are studied separately and the resulting bending moments at any particular section combined, a result would be determined which should be close to, if not actually, the true value.

As an illustration, investigate the chord member, 2–4, of the bridge studied by the writer in his paper. From the results given on pages 144 and 145 the maximum thrust is found to be 510 500 lb. and the vertical end moments are — 104 680 and + 335 800 in-lb. for Ends (2) and (4), respectively. The uniform dead load is estimated to be 16 lb. per in. and the moment of inertia is 2385.4 in.⁴ The horizontal end moments are + 275 040 and + 355 880 in-lb. for Ends (2) and (4), respectively, while the wind load, assumed to be acting on the outside of the chord, is taken as 6 lb. per lin. in., which is rather a high estimate. The moment of inertia to be used in this problem is 2852.45

* "Modern Framed Structures," Vol. III, Johnson, Bryan, and Turneaure.

in.⁴ The length of the member is 300 in. and E is taken as 30×10^6 lb. per sq. in. (See Fig. 119.)

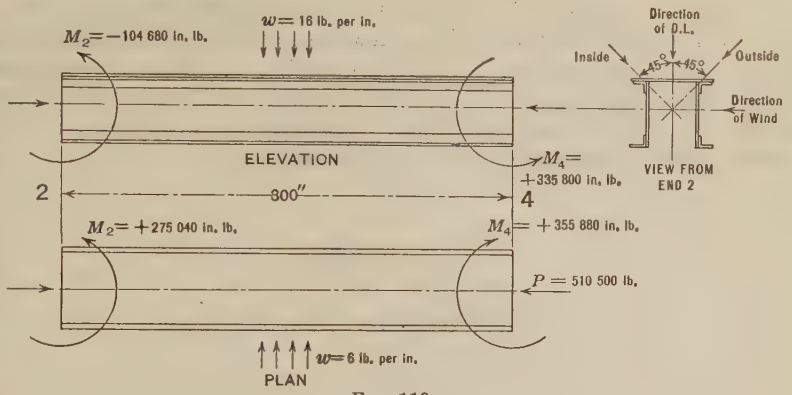

FIG. 119.

Consider the effect at the center: Equation (127) gives,

$$M_c = +\ 318\,360 \text{ in-lb. for the vertical plane.}$$

and

$$M_c = +\ 409\,380 \text{ in-lb. for the horizontal plane.}$$

The plus signs denote that the bending moments are increasing the compressive stresses in the top and the outside fibers, respectively.

By way of determining the effect in planes other than the vertical and horizontal, the two 45° planes were considered. For the plane inclined from the outside the combined end bending moments were + 120 460 and 489 090 in-lb. for Ends (2) and (4), respectively. The plane of bending is determined by $\tan^{-1}\left(\frac{I_x}{I_y}\cot 45°\right)$, that is, 39° 54¼′ to the horizontal, giving a moment of inertia of,

$$I_x \cos^2 39° 54\tfrac{1}{4}' + I_y \sin^2 39° 54\tfrac{1}{4}'$$

that is, 2 577.6 in.⁴ The bending moment at the center was found to be $M_c = +\ 515\,460$ in-lb. Similarly, the bending moment at the center for the plane inclined from the inside was found to be $M_c = -67\,740$ in-lb. The results, $M_c = +\ 318\,360$ and $M_c = +\ 409\,380$, for the vertical and horizontal planes combine to give $\frac{318\,360 + 409\,380}{\sqrt{2}}$ and $\frac{318\,360 - 409\,380}{\sqrt{2}}$, that is + 514 590 and − 64 360 in-lb., for the respective inclined planes. There are, therefore, differences in the results which seem to point to further research in the theory of unsymmetrical bending.

Assuming, however, that combinations of the results obtained from the vertical and horizontal planes give true values, consider the effect at the section, 200 in. from End (2). Equation (127) gives:

$$M_{200} = +\ 370\,750 \text{ in-lb. for the vertical plane}$$

and

$$M_{200} = +412\,590 \text{ in-lb. for the horizontal plane}$$

The particular section at which the most severe combined bending moment exists could be found by considering a few more sections. Assuming the 200-in. section as the critical one, + 370 750 in-lb. gives an additional compressive stress of 1 450 lb. per sq. in. to the outside top fiber, and + 412 590 in-lb. gives 1 446 lb. per sq. in. to the same fiber. The total stress, therefore, is 11 782 + 1 450 + 1 446 = 14 678 lb. per sq. in. in compression.

Paper No. 1575

FIRE-BANKS FOR OIL STORAGE*

By H. H. Hall,† M. Am. Soc. C. E.

With Discussion by Messrs. H. L. Shoemaker, Frank A. Epps, Ralph J. Reed, and H. H. Hall.

Synopsis

During 1924 larger quantities of petroleum and petroleum products have been in storage in the United States than ever before. Considering the quantity of this oil in storage and its generally inflammable nature, the fire loss has been remarkably low.

Refined oils (which comprise by far the largest part of oil storage in or near cities and towns), when ignited, simply burn quietly until they are extinguished or burned dry; but crude petroleums, and occasionally refined fuel oils, are liable to boil over while burning. In order to make the storage of these latter products as safe as that of the refined oils, it is necessary to surround the container with so-called fire-walls.

The service to be rendered by these structures is a peculiar one from an hydraulic standpoint, as their primary function is to withstand the single wave of oil thrown out by the "boil-over". In an effort to find the best possible design, the series of model tests here described was conducted, the outstanding result being a demonstration of the value of some form of flash-board or coping which will curl the advancing wave back on itself.

Introduction

The discovery of a number of extremely prolific petroleum pools in both Oklahoma and California during 1922 and 1923 has resulted, in spite of a rapidly growing market, in a considerable over-production of all forms of petroleum products. In round figures, oil in storage has increased since

* Presented at the meeting of June 3, 1925.

† Chf. Engr., Standard Oil Co. (California), San Francisco, Calif.

1921 from 200 000 000 bbl. to more than 500 000 000 bbl. This phenomenal growth has fixed the attention of many petroleum engineers on the design and proper protection of oil storage, with the result that a number of advantageous changes have been made. One of the most obvious changes, brought about by this study, has been a material increase in the size of storage units—both of the reservoir and the steel-tank type. Concrete-lined reservoirs have been built to contain more than 3 000 000 bbl. (42 gal. each); and steel tanks holding 150 000 bbl. per unit are not uncommon.

Among the changes looking toward better protection of the storage there has been a considerable extension in the use of fire-proof and vapor-proof roofs, and the addition of numerous devices which are intended primarily to prevent evaporation loss, but which incidentally improve fire protection by lessening or eliminating the escape of inflammable vapors.

Although in such carefully protected storage fires are a rather rare occurrence (particularly in California where the danger from lightning is small) the study of methods for guarding against the spread of fire has not escaped some scrutiny in connection with this general study of oil storage. Unfortunately, some of these products have a disconcerting habit of boiling over after burning for varying lengths of time. Recent studies have shown that these boil-overs are confined to crude, and, in some cases, to fuel, oils. In order to prevent the possible spread of burning oil from structures containing either of these products, it is necessary to surround them with a fire-bank or wall of such dimensions that it will not be topped by the sudden wave-like advance of the oil which has boiled out. Aside from this requirement, the fire-walls need not, in general, be able to withstand much static pressure. The boil-overs, while sudden and violent, do not as a rule discharge any large part of a tank's contents; and although occasional tank leaks occur, the complete collapse of a full tank is so rare as to justify the designer in almost neglecting this possibility. The fire-wall problem is, therefore, primarily a question of stopping a single wave of high velocity.

Lack of knowledge as to which oils are likely to boil over, as well as lack of attention to this principal requirement of fire-wall design, has had two unfortunate results. Occasionally earth fire-walls have been built so low as to be topped by burning oil; and frequently city authorities and fire protection engineers, in the absence of exact knowledge as to what emergency to expect and how to meet it, have insisted on excessive clearance distances and fire-wall requirements around oil storage. With a view to clearing up the general question of fire-wall design, both of the permanent and temporary types, Standard Oil Company of California decided to undertake a series of model tests. Ultimately, these included more than 1 000 miniature boil-overs (using water for most of the tests) directed against 66 differently shaped walls and other obstructions.

Apparatus

The principal item of apparatus used was a wooden trough representing, at a scale of 1 to 14, a segment extending radially from the center of a tank

115 ft. in diameter. (See Figs. 1 and 2.) At the tank end of this trough was placed a box from which the boil-overs could be discharged by jerking open a gate; the area of this box was made considerably larger relatively than that of a segment of the tank, with the thought that when a boil-over occurs, the frothing oil coming out of the tank is generally driven by the wind, so that most of it is concentrated on one side of the tank. The box was made adjustable so that the height from which the "spills" occurred could be varied, corresponding to different heights of tanks and refinery receiving "pans".

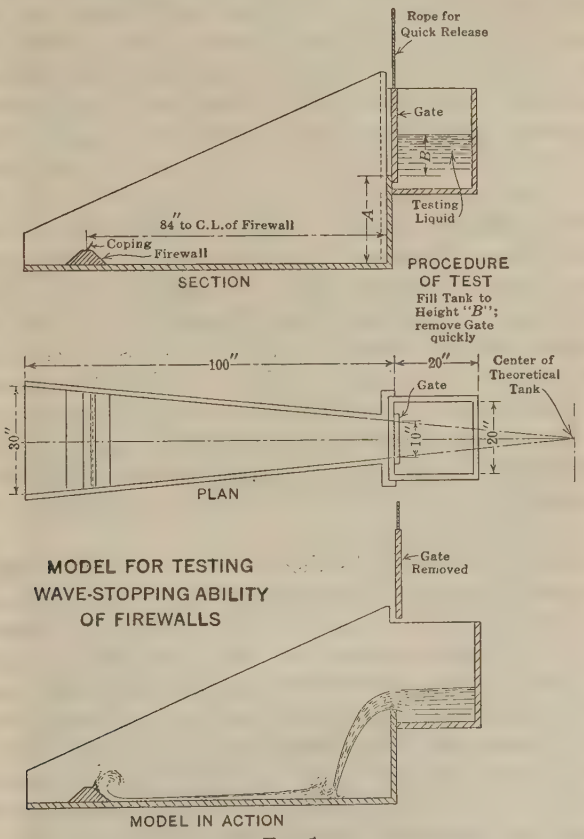

FIG. 1.

Model fire-walls were constructed, to the same scale, and placed at various locations in the trough. As shown in Fig. 1, the wall is at a distance corresponding to 100 ft. from the tank, this being common practice for walls surrounding tanks on comparatively level ground. A majority of the tests were made with the walls in this position; but data were also obtained for locations (to scale) 50 ft. and 20 ft. from the tank. Model walls of the following shapes were tested:

1.—Earth walls with a 1 on 1.5 side slope;

2.—Earth walls with a 1 on 1 side slope (Fig. 3, right);

3.—Vertical walls (Fig. 4, right); and
4.—Modifications of the foregoing, using copings of various sizes and shapes (see Figs. 3 and 4).

Procedure and Results

1.—Preliminary Tests.—Some preliminary experimenting was first done to determine (1) the way in which the gate releasing the water must be jerked open in order to obtain uniform results; (2) the criterion which should be used in judging the performance of different wall shapes; and (3) the effect of varying the height of the box from which the spill was discharged (Dimension *A*, Fig. 1). These tests are described in detail in the Appendix.

2.—Comparison of Standard Shapes.—The first main series of tests was run to compare the effectiveness of four of the most common shapes of wall now in use. The results are summarized by Curves 1 to 5, Fig. 5.

It will be noted that the curves for both shapes of earth wall, and for the plain vertical wall, are grouped close together, and have the same general shape and steep slope. Neither of these results is surprising, since all three shapes of wall depend primarily on height alone to stop the rush of water. This height, in turn, must depend approximately on the total energy of the oncoming stream, for the impact of the entire mass of water acts to push the topmost drops to a maximum height, with little loss in turbulence up to the time the spill takes place. As this total energy is approximately proportional to the square of the weir height, *W*,* it might be anticipated that the necessary height of wall, *H*, would vary approximately with the square of *W*. As a matter of fact, Curve 1 can be closely represented by the equation $H = 0.5\ W^{2.13}$.

In the case of the coped walls the situation is entirely different. Here, the principal part of the energy is expended in turbulence and shock when the coping turns the wave back on itself. The wall can be topped only when the energy of the oncoming stream is so great that all of it cannot be dissipated, and the remainder is sufficient to lift some of the water over the wall. Under these circumstances, as indicated by Curve 5, the height of the wall needs to be increased only approximately in direct proportion to the height of the weir. This result indicates that the efficacy of the coping as an energy absorber increases with the height of the wall and the violence of the wave—at least, over the range of heights covered by these tests.

Observation of the performance of the model coped walls during these tests showed that the effect of the coping is to turn all of the primary wave back inside the wall; in almost no case did any appreciable quantity pass over a coped wall in the first rush. The water turned back by the coping eventually piles up on that approaching from the tank until, after the velocity of approach is spent, there is for the instant a head causing flow over the wall. In any actual tank field a wave of oil would be free to spread out sideways, and it is probable that the secondary wave which tops the wall could not form

* The energy represented by the elevation of the bottom of the weir box above the floor board is not considered available, since it appears as vertical velocity and is largely dissipated in shock.

Fig. 2.—Front View of Test Apparatus, Showing Model Coped Wall in Place. The Wall Was Considered to Have Stopped the Wave When Not Enough Water Came Over to Cause Any to Run Off the "Tail-Board."

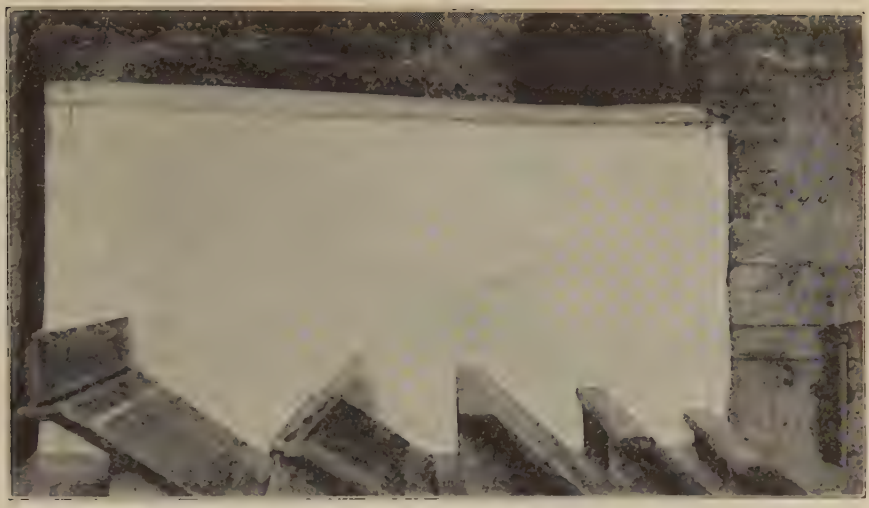

FIG. 3.—MODELS OF 1 ON 1 EARTH WALLS (PLAIN), AND 1 ON 1.5 EARTH WALLS WITH EXTENSIONS. ONLY THE FRONT HALF OF THE WALL WAS REPRODUCED, AS THE BACK HALF WOULD HAVE NO BEARING ON THE RESULTS.

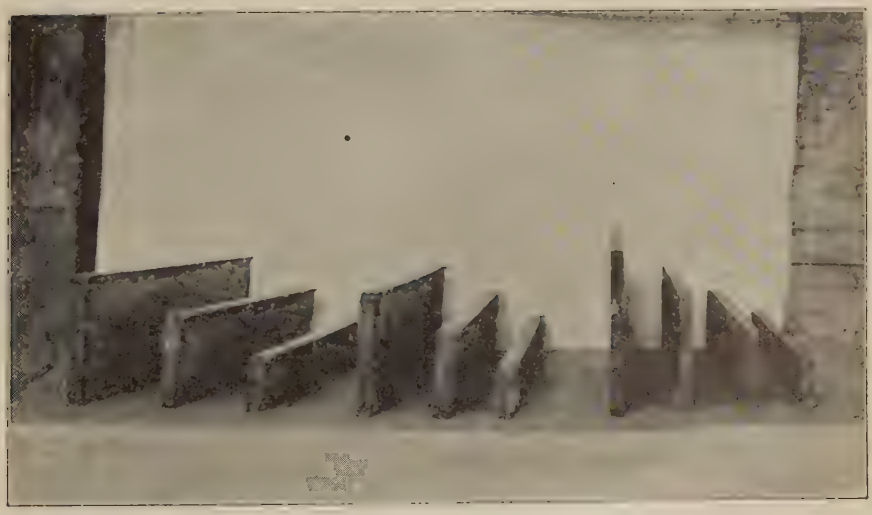

FIG. 4.—MODELS OF VERTICAL WALLS, PLAIN AND WITH COPINGS.

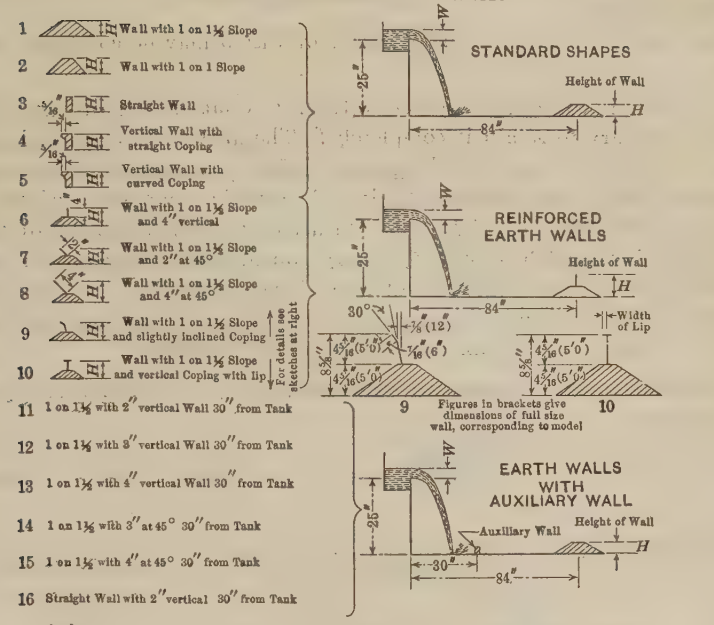

NOTE: Models were made to represent a Tank 30′ high with C.L. of firewall 100′ from the shell. Actual Scale used was 1:14; so that roughly 1″=1′+

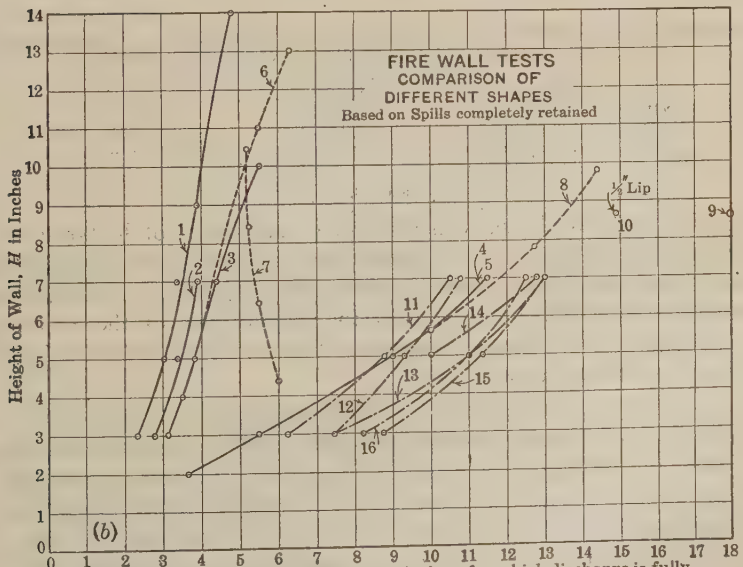

FIG. 5.

so easily as in the experimental model where the water is closely constrained by the side-walls.

The results indicated by these curves of Fig. 5 may be compared from two points of view:

(*a*) With a boil-over of given intensity, what height of each shape of wall is necessary to retain it completely? The answer is obtained by reading from the curves of Fig. 5 the heights of different walls that will stop a given "height of weir", for instance, 3½ in. A graphic comparison of the results is shown in the top row of Fig. 6. On account of the steepness of the slope of Curves, 1, 2, and 3 of Fig. 5, a very considerable difference in height is observed between the walls of different shapes necessary to stop this 3½-in. discharge. Furthermore, it may be noted that a coped wall of less than one-half the height of the straight wall will be equally effective.

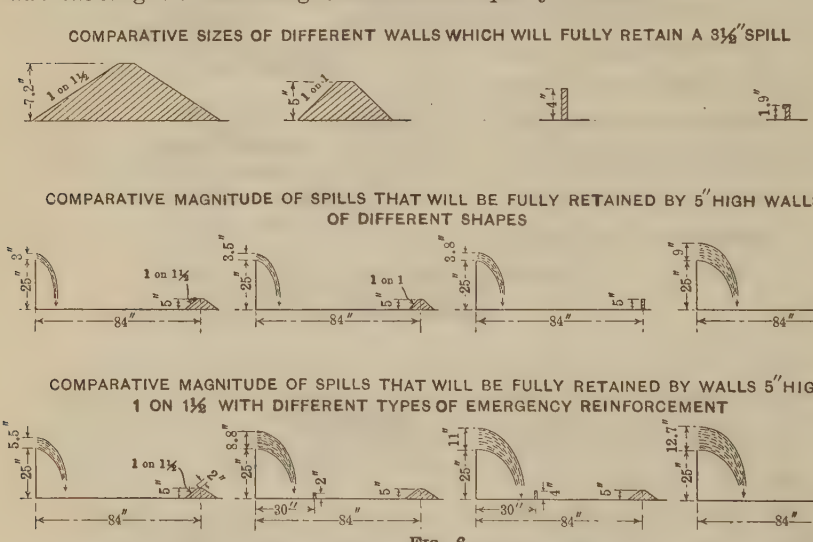

FIG. 6.

(*b*) With walls of the same height, what magnitude of boil-over will be stopped by different shapes? The middle row of Fig. 6 gives this comparison graphically for walls 5 in. high. When judged by this criterion, there is comparatively little difference between the effectiveness of the sloped walls and of the plain vertical walls; whereas, the coped vertical wall is almost three times as effective as any other.

The outstanding feature of these two comparisons is the effectiveness of the coped wall. This is further emphasized by the detailed curves for the different walls shown in the Appendix (Figs. 17 and 18). It will be noted that the curves for walls with sloping sides (Fig. 17) ascend rather steeply, whereas, the curves for the straight and coped walls (Fig. 18) are relatively flat. Considering, for example, the case of a 10-in. spill discharged against walls, 5 in. high, it will be noted that 40% of this spill passed over the 1 on 1.5 wall (Fig. 17), while under like conditions less than one-half of 1% passed over the vertical wall fitted with a coping (Fig. 18). Thus, while the actual "dry-points"

plotted on Fig. 5 are probably the most conservative criterion on which to judge the different shapes, it appears that a wall which permits not more than 1% of the spill striking it to pass over may be regarded as satisfactory under most conditions. The curves on Fig. 19 have been plotted to compare the different shapes on this basis. It will be noted that the coped walls make an even more favorable showing in comparison with the walls having sloping sides.

3.—Methods of Reinforcing Standard Walls.—

(*a*).—Extension on Top of Wall.—A method that has been used to some extent for increasing the effectiveness of earth walls has been to place on top of them a vertical extension consisting of scrap steel plates. The models of walls with a 1 on 1.5 slope were equipped with such extensions 4 in. high (representing an actual height of about 5 ft., see model at the left in Fig. 3). The results are plotted as Curve 6 of Fig. 5. It will be noted that this extension resulted in comparatively little increase in the effectiveness of the wall, judged on the basis of complete stoppage of the wave. However, in testing this model it was found that the extension markedly reduced the percentage of the larger spills that passed over the wall.

Observation of the behavior of this coped wall indicated that it would be desirable to tip the extension in toward the tank instead of leaving it vertical. This was accordingly done, with the results shown on Curve 8, Fig. 5. It will be noted that this greatly increased the effectiveness of the wall. (See, also, Figs. 7 and 8.) Tests were run using extensions sloped at both 30° and 45° from the vertical. No appreciable difference in the results could be observed. As the 30° slope would probably be more convenient in actual practice, it is to be recommended.

This 4-in. "coping" proved so effective it was felt that an extension of one-half the height (still tilted back toward the tank) would give satisfactory results. This was tried, with the results shown by Curve 7 of Fig. 5.

It will be noted that even this small reinforcement materially increased the effectiveness of the wall, particularly at lower heights. The shape of this curve, indicating as it does that high walls will not stop such large boil-overs as low ones, is peculiar; but it has been carefully checked and found to be correct. The explanation seems to be that, with such a small coping, the long slope of the higher walls gives the force of the wave such a strong component in an upward direction that the coping is less able to break it up than when placed on a lower wall with a shorter approach.

In discussing the practical application of these "copings", it was suggested that if they were sloped back toward the tank at an angle of 45°, or even 30°, there might be danger that burning oil discharged against the base of the fire-wall in a preliminary "slop-over" would so warp the sheets that they would not be in shape to function at the time of the main boil-over. Tests were accordingly run using the shape numbered "9" on Fig. 5, in which the coping was placed in an almost vertical position, with a short lip at the top turned back at a somewhat sharper angle. Only one height of this shape was tried, as shown by a single point on Fig. 5, but it will be noted that this point is well to the right of the others, indicating that this shape was the most effective of those tested. (See, also, Figs. 9, 10, and 11; the "wings"

shown in Fig. 11 were used in testing the other coped walls, as it was felt that the corner effect observed in these models would not obtain in practice and tended to obscure the real effectiveness of the different walls). From the results obtained with this model it is felt that a wall and coping of the dimensions shown in the detailed Sketch No. 9, Fig. 5, would completely turn back the wave from the most severe boil-over likely to occur in practice, provided the wall is 50 ft. or more from the tank.

It was next suggested that for reinforcing division walls between two tanks, a vertical coping with a horizontal lip on top, as shown in Sketch No. 10, Fig. 5, would be desirable. Tests were accordingly made on a model of this shape, using four different widths of lip. The result obtained with a ½-in. lip (corresponding, for the scale of model used, to a 7-in. extension on an actual coping) is plotted as the single point marked "10" on Fig. 5. It will be noted that this shape also proved very effective, so that a division wall of this shape with a 1-ft. plate at the top of the coping (giving a 6-in. lip on each side) can be counted on to turn back any boil-over, if the wall is at least 75 ft. from the tanks protected. Where conditions require that the wall lie closer to the tank, a wider lip would be desirable—perhaps with a maximum projection of 1 ft. on each side if the wall is within 40 or 50 ft.

(*b*).—Auxiliary Walls Close to Tank.—A study of the behavior of the waves created in those different tests suggested that by breaking the force of the wave just as it struck the ground the effectiveness of the fire-walls would be increased. Tests were accordingly made, first, with a small vertical wall placed 30 in. from the spill-box (corresponding in actual size to a vertical wall a little more than 2 ft. high, approximately 35 ft. from the tank shell). The results are shown in Curve 11, Fig. 5.

It will be noted that this small auxiliary wall had an important influence in increasing the effectiveness of the different types. Comparing Curves 11 and 7, (Fig. 5), it will be noted that in the case of the higher walls the same 2-in. strip used as a vertical wall near the tank was almost twice as effective as when placed as a coping on top of the wall. Since the auxiliary wall 35 ft. from the tank would be only about 60% as long as that 100 ft. away, the considerably smaller quantity of material needed for the closer wall is a further argument in its favor.

When 4-in. strips were used (corresponding approximately to a 5-ft. steel plate), this superiority of the closer wall was not so marked as far as stopping the wave was concerned (compare Curve 8 with Curves 13 and 15), but, of course, its advantage in requiring less material still remains.

Placing the auxiliary wall close to the tank either in a vertical position, or inclined back toward the tank, seemed to make comparatively little difference. Curve 12 applies to a 3-in. vertical wall, and Curve 14 to the same wall inclined at 45 degrees. Curves 13 and 15 give a corresponding comparison between 4-in. walls.

Curve 16 (Fig. 5) brings out the fact that the auxiliary wall close to the tank is just as much of a help to vertical fire-walls as it is to those inclined to a 1 on 1.5 slope. A 2-in. auxiliary wall close to the tank resulted in moving

FIG. 10.—END OF 18-INCH BOIL-OVER; A SLIGHT QUANTITY PASSING OVER THE WALL AT THE CORNERS.

FIG. 11.—18-INCH BOIL-OVER COMPLETELY STOPPED, USING "WINGS" TO ELIMINATE CORNER EFFECT.

TESTS OF MODEL WALL No. 9 (FIG. 5).

Curve 3 (for the plain straight wall) out to the position of Curve 16, which shift strikingly emphasized the effectiveness of breaking the force of the wave by having an auxiliary wall close to the tank.

The bottom row of Fig. 6 gives a graphical comparison of the effectiveness of the different types of reinforcement discussed. As indicated, the main fire-wall in each of these tests was a 5-in., 1 on 1.5 wall. Comparison of the sizes of the spills mentioned, with that which the same wall without any reinforcement will stop (shown as the first diagram of the middle row) emphasizes the value of some type of reinforcement to ordinary 1 on 1.5 walls.

(*c*).—Borrow-Pits, Etc., Close to Tank.—It was next decided to see whether a pit dug around the base of the tank in such a way that the falling wave would strike the ground surface approximately normally (with the idea of creating maximum turbulence), would produce an effect similar to that of the vertical auxiliary walls. The floor of the model trough was modified to provide such a pit 3 in. deep; the results are shown as Curve 3 of Fig. 12. The plain 1 on 1.5 wall is also plotted for comparison. It is evident that the value of the plain wall has been only slightly increased by this arrangement.

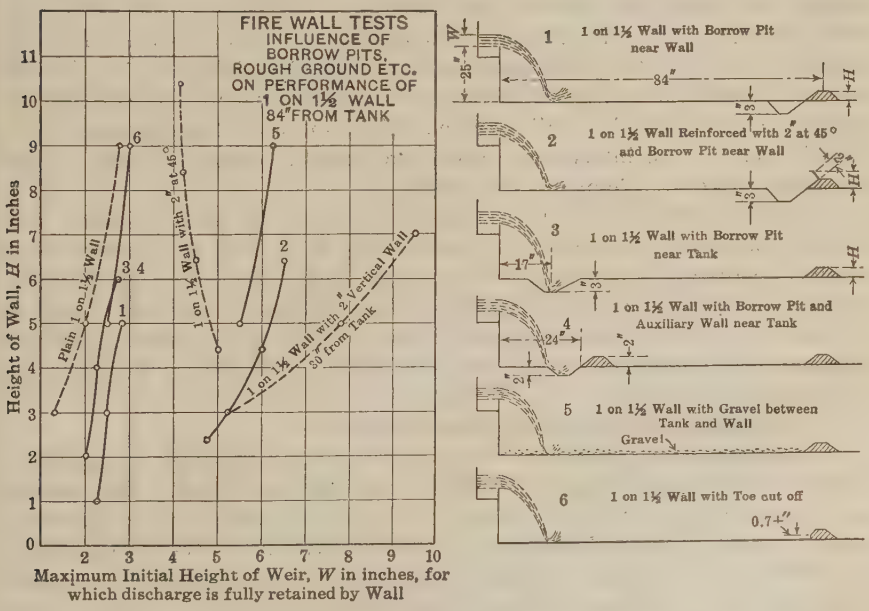

FIG. 12.

It was then suggested that a low earth wall built just outside the pit might increase its effectiveness. Curve 4 of Fig. 12 (which coincides with Curve 3) gives the results for a pit 2 in. deep with a 2-in. wall on the outside. This indicates that the wall on the outside makes a 2-in. pit as effective as a 3-in. pit without the wall; and as this would be the logical shape in which to place

the dirt, it is recommended. The slope toward the tank should be made as steep as soil conditions permit.

(*d*).—Borrow-Pit at Wall.—During the progress of the tests interest was expressed regarding the possible effectiveness of a borrow-pit on the tank side of an earth wall. The floor of the model trough was accordingly modified with results as indicated by Curves 1 and 2, Fig. 12. It will be noted that the pit next to the wall proved somewhat more effective than the one near the tank already described in Section (*c*) (compare Curve 1 with Curve 3), and considerably increased the effectiveness of a small coping at the top of the wall (compare Curve 2 with the dotted curve for "1 on 1.5 wall with 2 in. at 45°"). This is a further argument in favor of using a coping on top of 1 on 1.5 walls; for there is generally a borrow-pit on the tank side of such walls.

(*e*).—Rough Surface Between Tank and Wall.—In actual practice the space between the fire-walls and tank is sometimes cleared of weeds with a road scraper, which leaves the surface quite smooth; in other cases, the weeds are simply plowed under, leaving a rough surface.

With a view to determining the influence of such a rough surface on a boil-over wave, a strip of tarred paper was laid on the bottom of the model trough, into which was bedded gravel approximately ¼ in. in diameter and less. To scale, these bits of gravel simulated clods about 4 in. high. The results of tests with this equipment are shown as Curve 5 on Fig. 12. It will be noted that the gravel had a marked effect in breaking up the force of the wave, and this enabled a wall of given height to stop a much greater spill than it could if the intervening space were smooth (compare Curve 5 with the dotted curve for "Plain 1 on 1.5 Wall").

(*f*).—Toe Cut-Off, 1 on 1.5 Walls.—In cleaning up around certain fire-walls, it has been the practice to cut off the toe of the wall, on the tank side, leaving a vertical face about 1 ft. high at the base. Tests were requested to determine the influence of this change on the effectiveness of the wall. Curve 6 of Fig. 12 shows that, as in the case of borrow-pits, this expedient, while it does move the curve in the right direction, adds only slightly to the effectiveness of the plain wall.

(*4*).—*Effect of Placing Walls Closer to Tank.*—

(*a*).—Wall 50 Ft. from Tank.—The model walls were next set in a position corresponding to a distance of 50 ft. from the tank shell. The results are summarized by the curves on Fig. 13. It will be noted that the different shapes showed, in general, the same relative behavior as in the previous tests.

At this closer distance the effectiveness of the vertical wall, as compared with the 1 on 1.5 wall, was relatively greater than at the 100-ft. spacing. On the other hand, the coping on top of the vertical wall did not result in such a marked increase in its effectiveness as had been previously observed. This led to the suggestion that a heavier coping might be desirable; a comparison of Curves 3 and 4 of Fig. 13 indicates that doubling the width of the coping increased the effectiveness of the wall by about 20 per cent. The coping on top of the 1 on 1.5 wall showed the same marked effectiveness as in the previous tests (Curve 5 of Fig. 13).

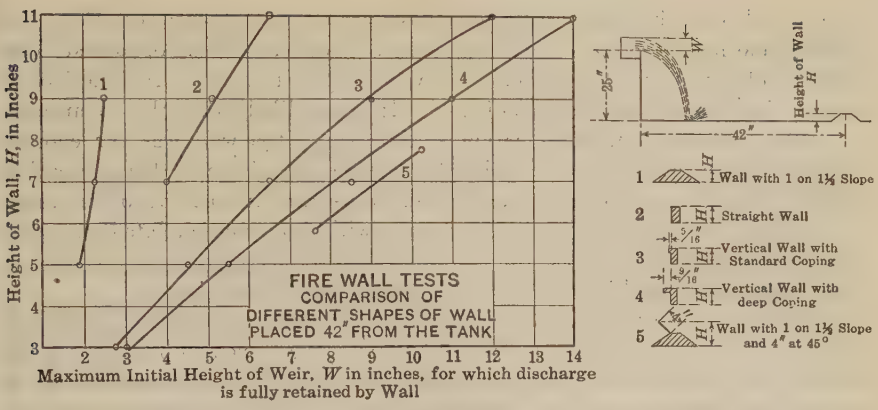

FIG. 13.

(*b*).—Wall 20 Ft. from Tank.—When the model walls were moved in to a distance (17 in.) corresponding to 20 ft. from the tank shell, the differences in the behavior of the various shapes were not so marked. The curves on the upper half of Fig. 14 show the results when the boil-overs were discharged from the 25-in. height used in previous tests (corresponding to a 30-ft. tank); and the data on the lower half summarize the results of a few tests in which boil-overs were discharged against low walls from a height of 8½ in., corresponding to the 10-ft. "receiving pans" commonly used in refineries.

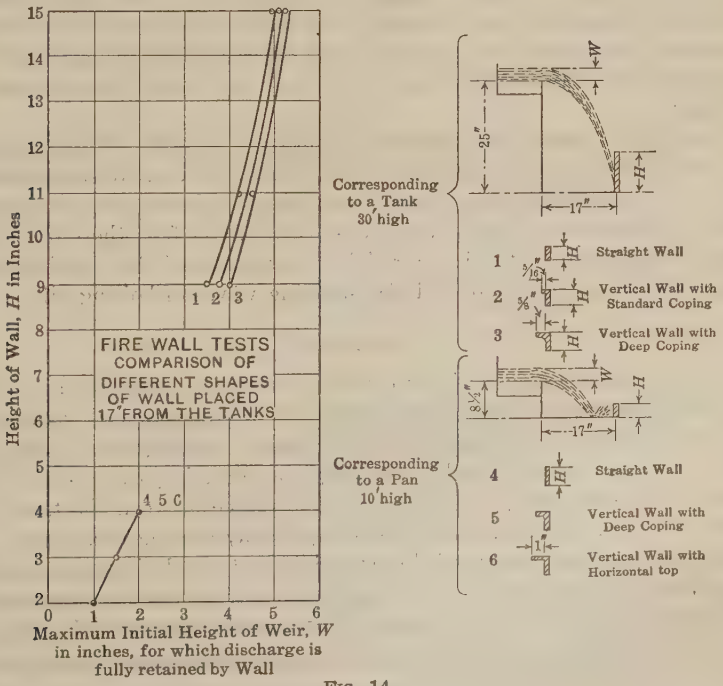

FIG. 14.

It is felt that the small differences indicated by these tests (Test 4(*b*)) are attributable mainly to the fact that, when the model walls were moved close to the tank, there was hardly room for wave action to occur. In practice, of course, these conditions would not hold. It seems likely that the advantages of copings observed in those previous tests where the wall was far enough away from the tank for wave action to develop, would make themselves felt to practically the same extent where actual walls are within 20 ft. of the tank.

5.—Reservoir Fire-Walls.—In connection with some contemplated strengthening of reservoir fire-banks, tests were requested to determine the influence of a small mound and borrow-pit at the toe of a reservoir slope.

As was the case with the vertical auxiliary walls near the tank, described under Test 4(*b*), the mound at the base of the slope served to break the force of the wave to such an extent as to enable a given height of main wall to stop a much larger wave; or, conversely, with a given intensity of boil-over to stop, the main wall can be made considerably lower if the auxiliary mound is built at the toe of the slope.

Since a relatively small quantity of earth is required to build this mound (both on account of its low height and small radius as compared with the main fire-wall), the total yardage of earth required to obtain a given degree of protection is 20 or 30% less when the mound is used, than when the main wall is built high enough to stop the wave without any auxiliary protection.

6.—Tests with Foam Solutions.—In the tests previously described, water was used on account of its convenience. However, in discussing some of the results, it was suggested that it would be interesting to use a liquid that froths and expands as it pours out of the tank, thus simulating conditions when burning oil boils over. To accomplish this, it was decided to use weak foam solutions.*

It was found that when these solutions were suitably diluted, the waves produced seemed to act in much the same way as a wave of frothing and steaming oil. The different shapes of wall were found to have essentially the same relative effectiveness as when water was used. It is felt, therefore, that the results of the water tests give a reliable indication of the relative value of different types and heights of wall for stopping waves of boiling oil.

Conclusions

The outstanding result of these tests (which comprised a total of more than 1 000 "boil-overs" discharged against 66 different model walls or combination of walls) is the value of some form of velocity or energy "killer" other than mere height of wall. Probably the most important of the experiments tried is the coping, although a rough surface between the tank and the wall and the auxiliary walls and pits will probably each have a place.

The practical application of this principle to typical oil-storage conditions is illustrated in Fig. 15. Several concrete walls of the recommended form have already been built. On most of these walls, however, the coping has

* Basic and acid liquids used to produce foam for extinguishing oil fires, see U. S. Bureau of Mines, *Bulletin No. 170*, p. 10.

been made only about 4 in. wide. The tests have indicated that a heavier coping—say, 8 in. wide—will add considerably to the effectiveness of walls which are fairly close to tanks; and as this increase in the width would add a negligible amount to the cost, it would seem desirable.

As indicated by the curves on Fig. 13, a wall 5 ft. high (model height, 4.3 in.) with an 8-in. coping is as effectual as a plain wall 9.6 ft. high (model height, 8.2 in.). A 5-ft. coped wall of standard T-shape will require about ¼ cu. yd. of concrete per lin. ft. at $30 per yd.; this would cost $7.50 per lin. ft. A wall, 9.6 ft. high, would contain about 0.6 cu. yd., costing about $18. From these figures it is apparent that a given degree of protection for turning back a wave will cost only about one-half as much with a coped as with a plain wall.

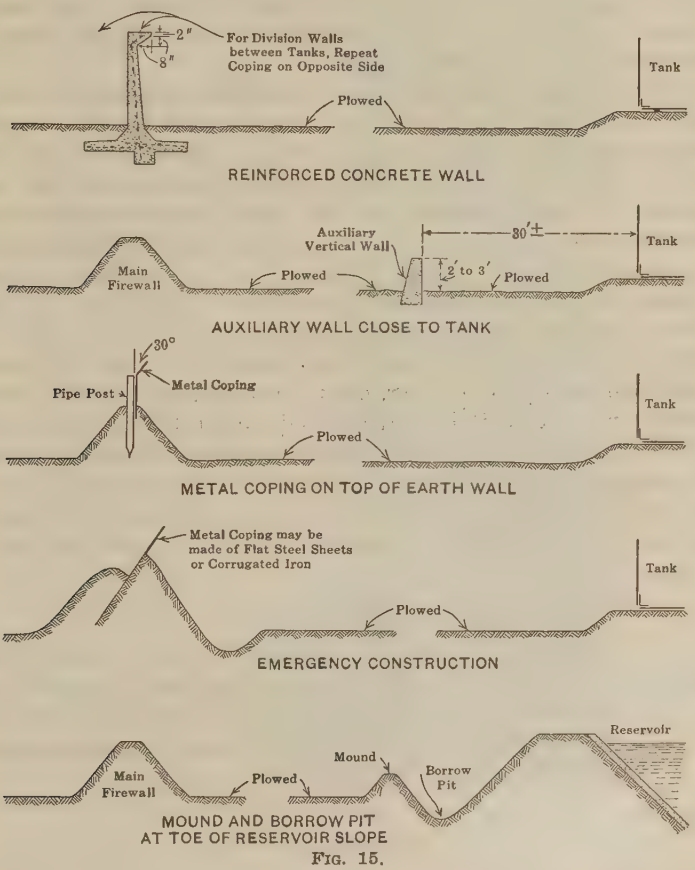

FIG. 15.

An even greater economy is effected by the use of copings on earth walls. Over these, on account of their sloping sides, waves have a tendency to pass readily; but as soon as a 3 or 4-ft. coping is placed at the top, a wall 5 ft. high becomes much more effective than an uncoped wall 15 ft. high. (See curves on Fig. 5.) Where scrap steel plates are available for building copings of the general form shown on Fig. 15, the cost will be very low. Even

where new galvanized-iron sheets have to be purchased, the cost figures indicate that a given effectiveness can be obtained with a coped wall at about one-quarter the cost of the high earth wall.

Where local conditions permit, a low vertical auxiliary wall about 30 ft. from the base of the tank is an even more economical method of increasing the effectiveness of the main wall. This auxiliary wall breaks the force of the wave and robs it of the energy required to carry it over a main wall that it could otherwise easily surmount. On account of the smaller radius of this auxiliary wall, only about 60% as much material is required to build it as for the coping on the main wall that would have equivalent effect.

A small mound 2 or 3 ft. high with a borrow-pit toward the tank, and the slope made as steep as soil conditions will permit, will produce an effect similar to these small auxiliary vertical walls; but on account of the relative ease with which the wave passes over a wall with sloping sides, the mound is not nearly so effective as the vertical wall.

The same principle of breaking the force of the wave just as it starts can be applied in the case of reservoirs by building a small mound just at the toe of the reservoir slope. Another application of the same general principle consists of roughly plowing the surface of the ground between the tank and the fire-wall. The tests indicated that this would serve to break up the energy of the waves sufficiently to enable a given wall to stop a considerably higher boil-over than if the surface between the tank and the wall were smooth.

A factor which adds materially to the value of this study has been the possibility of applying the principle to emergency construction. This was well illustrated in a recent crude-oil fire in the Midway Field in California. Four large tanks burned and boiled over, but the management was able to save the pump-house and other buildings distant only about 160 ft. from the nearest tanks, by throwing up emergency earth walls against the back of which were placed corrugated galvanized-iron sheets which projected several feet above the top of the wall and thus provided a coping tipped toward the fire. These walls proved entirely effective in stopping the boil-over and saving the buildings. (See Fig. 16.)

Personnel

The tests herein described were conducted by the Technical Staff of Standard Oil Company of California under the direct supervision of the writer. The equipment was designed by Mr. A. Kremser, the tests were actually made by Messrs. H. J. Berg and E. F. Post, and the results collated by Mr. G. O. Wilson.

APPENDIX

Preliminary Tests to Study Theoretical Applicability of Model and Performance of Apparatus

Theory of Model Application.—Although it was never intended to make quantitative use of these model experiments, it was hoped that in spite of the small scale they would show relative efficiencies among themselves. A number

Fig. 16.—Emergency Wall Used in Actual Fire.

of exhaustive studies of the application of models to various engineering problems have been presented in recent years. In their paper* describing the experiments with models of the Gilboa Dam, R. W. Gausmann, M. Am. Soc. C. E., and C. M. Madden, Assoc. M. Am. Soc. C. E., stated that "if a model of a weir or channel is geometrically and mechanically similar to its prototype, the velocity will vary as the square root of the scale ratio."

In the model experiments here considered, the criterion of comparison is the height of wall which will be topped by various spills. As this height will be approximately proportional to the square of the velocity, and as the velocity, in turn, will be in proportion to the square root of the scale ratio, it would appear that the results of these experiments will be approximately in direct proportion to the scale ratio; or what is more important, will show approximately true relative proportions between different tests.

Performance of Apparatus.—In the first trials of the apparatus it was observed that considerable difference in the behavior of the wave resulted from apparently minor variations in the method of opening the gate. A standard procedure therefore was adopted in which the operator stood in a certain place and jerked the rope hard enough to throw the gate up with considerable impact against the supporting beam.

The next point to be investigated was the proper criterion for judging the performance of the different shapes and heights of model walls to be tested. It was at first felt that the maximum height of spill which any given shape should be credited with retaining was that for which the top of the wall and the space in the end of the trough outside the wall (designated by *A* in Fig. 2, and spoken of hereafter as the "tail-board") remained absolutely dry. It was found, however, that this depended too much on accidental splashing when the wave hit the wall in some peculiar way; and it was finally decided that the criterion should be the condition where not enough water splashed over the wall to cause any measurable quantity to run off the tail-board.

To check the accuracy of the so-called "dry point" thus determined for each wall, the following procedure was adopted: Starting with a spill which would be large enough to throw a considerable percentage of water over the wall, a series of runs was made, gradually decreasing the size of spill until the dry point was reached. Several more runs were made after reaching this point with still smaller quantities, to make sure that these would be completely retained by the wall. By placing at the end of the tail-board a collector pan discharging into a 5-gal. can, the quantity of water passing over the wall in each test could be measured. These quantities were plotted as a percentage of the total quantity discharged in any given spill; and the intersection of the curve thus obtained with the base line gave a good check on the accuracy of the dry-point found. The curves of Figs. 17 and 18 are typical examples of these "percentage over" curves, whereas the final summarizing curves, Figs. 5, 12, 13, and 14, show only the dry points for the different sizes and shapes of wall. As explained (page 235), Fig. 19

* *Transactions*, Am. Soc. C. E., Vol. LXXXVI (1923), p. 300.

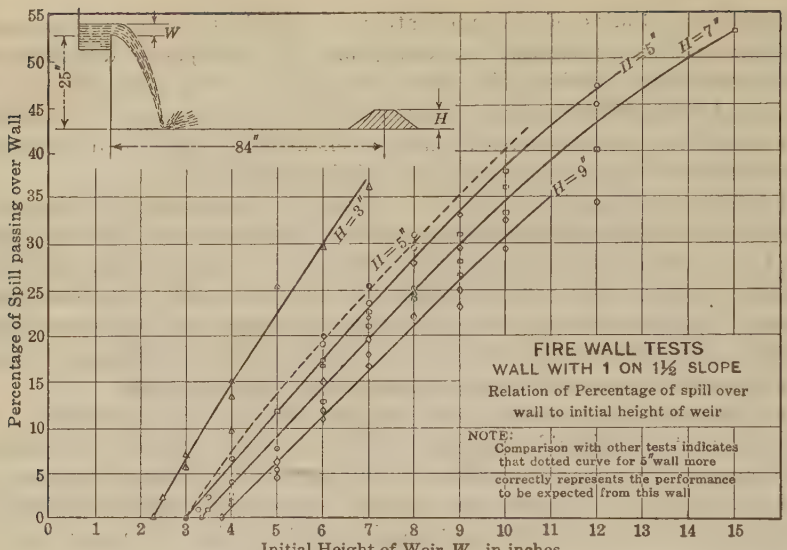

FIG. 17.

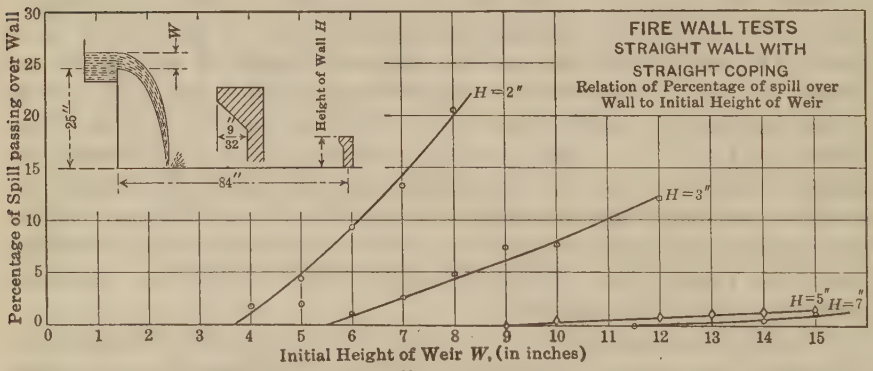

FIG. 18.

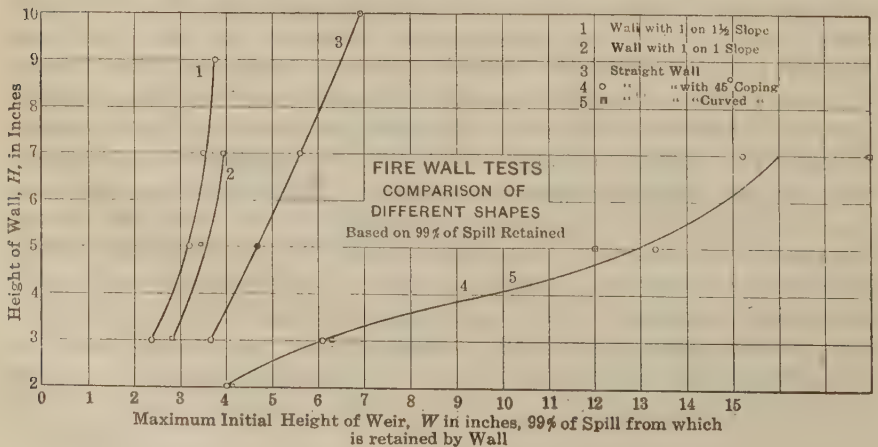

FIG. 19.

compares the different shapes on the basis of 99% of the spill being retained, instead of 100% as in Figs. 5, 12, etc.

One other preliminary step before starting the actual comparison of different sizes and shapes of wall was to investigate the effect of varying the height of the box from which the spill was discharged (Dimension *A* in Fig. 1). The relative effectiveness of different walls was found to be (within reasonable limits of experimental error) essentially the same regardless of whether the spill was delivered from a high or low box. Accordingly, it was decided to run most of the main tests with the box set at 25 in. above the floor, which corresponds to an actual tank height of 30 ft.—this being the height most commonly used by Standard Oil Company of California.

DISCUSSION

H. L. SHOEMAKER,* ESQ.—The practical results and conclusions at which the author has arrived, have not only been approved by the entire petroleum industry of the United States, but they have been used in a very practical way.

Mr. Hall's report was first presented at the Convention of the American Petroleum Institute in December, 1924, at Fort Worth, Tex., where his work was commented on very favorably by the oil industry. A committee of which the speaker was Chairman, collected and compiled data in regard to the hazards of petroleum products in storage, and found some astounding figures. The Committee was also able to use many of Mr. Hall's data, especially in relation to the problem of the spacing of above ground petroleum storage tanks.

Regarding the fire record of petroleum products in storage in the United States, extending over a period of ten years (1915-25), eighty-seven oil companies, including all the large companies operating in the country, submitted the following information covering their fire history: In this period, 143 refineries experienced 73 fires, or 1 fire per plant in 20 years. In 11 132 marketing stations (ordinary bulk distributing stations where petroleum products are received by tank car, unloaded into storage, and distributed by tank truck), which embrace the territory from the Pacific Coast to the Atlantic seaboard, inclusive, and many of which are within the corporate limits of cities and built-up communities, 19 fires were experienced in the 10-year period mentioned, or 1 fire per plant in 5 860 years.

Regarding large seaboard terminals and pipe-line terminals, 273 such properties reported 77 fires in the 10-year period, or 1 fire per plant in 35 years; and 713 tank farms, probably representing a storage capacity of 500 000 000 bbl. of crude oil, experienced 88 fires in the same period, or 1 fire per plant in 81 years.

The oil industry feels that this constitutes a very remarkable fire record. Expressing the statistics in other terms and establishing a fire frequency ratio, or the number of fires in tankage compared with the number of tanks in service, it is found that 15 873 all-steel gasoline tanks had 41 fires in the 10-year period, or a frequency ratio of 0.026% per year, and that 12 594 all-steel kerosene and refined oil tanks experienced 35 fires in the same period, or a fire frequency ratio of 0.028% per year.

It is interesting to compare these annual fire ratios, or percentage of tanks lost by fire per year, with similar figures covering dwelling houses. The number of dwelling houses in the United States in 1920† was approximately 20 697 204 The number of fires in such dwelling houses per year‡ was 131 035, or expressed as an annual fire loss ratio, or percentage of dwellings burned per year, equals

† World Almanac, 1925.

‡ "Safeguarding America Against Fire", December, 1924.

0.63%, as compared with petroleum tank ratios mentioned of 0.026% and 0.028% for gasoline and refined oil products, respectively.

In view of the fact that the petroleum industry was vitally concerned with possible State and municipal regulations regarding the handling and storing of petroleum and its commodities, which might govern the construction of tanks, fire-walls and other requirements, the statistics given were of immense value. The Committee reporting on this work to the industry mentioned previously, in making recommendations regarding spacing of tanks, found Mr. Hall's work of immense practical value. To illustrate, in spacing crude oil tanks it was determined that a tank should be at least two diameters from shell of tank to adjacent property line in order to protect such property in case of fire. One of the essential reasons for recommending this distance was that Mr. Hall's data indicated that, to be fully effective, a fire-wall must be placed approximately one diameter from the shell of the tank. Further, most ordinances specify capacity as a requirement in fire-wall construction around oil tanks. As shown by Mr. Hall's paper, capacity of a fire-wall is only one factor. The horizontal distance of the fire-wall from the container, as well as the type of construction used (that is, the kind of coping or lack of coping), are of more practical importance in protecting life and property and in retaining "boil-over" waves than mere capacity inside the wall or dike.

Frank A. Epps,* Esq.—The oil industry has been intensely interested in the valuable data presented in this paper and also in a supplementary investigation conducted by Mr. Hall.† While this paper deals with fire-bank protection required for oils possessing "boil-over" characteristics, the fire-bank requirements for tanks containing oils not possessing "boil-over" characteristics are also of interest.

Mr. Hall has stated, and it is a well-known fact, that refined oils do not "boil over". Clearly then, for this type of oil storage, the fire-bank can serve only as a secondary container in case of spills, leakage, or rupture of the tank. Except under unusual conditions, the oil industry has very strongly questioned the necessity or advisability of fire-banks solely for such purpose. Fire-banks capable of retaining at least the entire tank contents cost a great deal in proportion to the remainder of the installation in which refined oils are usually stored. It is questionable whether the benefit of protection obtained from this expenditure is worth the cost. To answer this and other questions, a committee of the American Petroleum Institute was appointed to secure and analyze the complete tank-fire record of the oil industry in the United States for the 10-year period, 1915-25. The following is quoted from the report:

"* * * fire-walls surrounding gasoline and refined oil tanks were called upon to prevent the spread of fire in but 8 cases in 10 years. In 12 other cases fire spread because of the non-existence of fire-walls. Thus, fire-walls were effective or could have been effective in 10 years in only 20 instances. It is conservatively estimated that the fires reported represent the fire experience of not less than 50 000 steel-roofed tanks in service. Thus, fire-walls sur-

* Mgr., Fire Protection Dept., Tide Water Oil Co., New York, N. Y.

† *Mechanical Engineering*, July, 1925, p. 540.

rounding these 50 000 tanks could have been of practical benefit in only 20 instances—this in a 10-year period—or 2 per year.

"The Committee believes that this record of experience demonstrates the injustice of requiring elaborate fire-wall construction and the needless expense caused thereby, for the protection of this class of storage."

With respect to fuel oils, this Committee was able to obtain a record of only fourteen fires, in only one of which would a fire-wall have been of any practical benefit. The Committee felt, therefore, that the danger of fire in fuel-oil tankage is so extremely low as not to justify the cost of any fire-bank protection whatsoever.

Regarding fire-banks for crude oils, it is a peculiar fact that aside from the petroleum industry itself, fire-protection circles have regarded fire-banks merely as secondary containers, the function of which is to hold the contents of the tanks surrounded in case of spills, leakage, or rupture. Considerations affecting the fire-bank's capabilities of withholding a wave of burning oil thrown out of a tank by a "boil-over" have not received a great deal of attention; this, in spite of the fact that it has been generally recognized that the average fire-bank was not effective under this condition. Fire-protective legislation and insurance requirements to date have considered only the capacity of the enclosure and the material of which it is built, capacity, the chief specification, being usually 150% of the tank contents. The research work conducted by Standard Oil Company of California under the direction of the author has clearly demonstrated that capacity alone is not a measure of fire-wall effectiveness when the tank contains crude oil.

The Committee of the American Petroleum Institute reached the conclusion that the bank around a crude oil tank must function both to throw back the wave of burning oil and to contain the liquid ejected. The usual "boil-over" from a crude tank seldom exceeds 10% of the tank contents. On the other hand, there may be several "boil-overs" during the same fire, also records are available wherein "boil-overs" are reported to have ejected more than 10% of the tank contents. The fire-bank must contain or hold this oil, not to mention large quantities of water often thrown upon the sides of the burning tank to keep it cool. The Committee felt, therefore, that a definite capacity specification should be provided. After investigating the research work performed by Standard Oil Company of California and likewise considering the tank-fire record of the United States for the last ten years, the Committee reached the conclusion that:

"Above ground, gas-tight containers for crude oils should be surrounded by fire-walls or dikes of earth or other suitable material, and should be:

"(*a*) Of a capacity equal to that of the tank or tanks surrounded, unless adequate drainage to a sump of like capacity is provided;

"(*b*) Located not nearer to the shell of any of the enclosed tanks than the diameter of the largest tank enclosed, and in any case not less than 50 ft.;

"(*c*) Provided with a suitable coping projecting inward to turn back boil-overs."

Mr. Hall's research work had a great deal to do with the formation of that recommendation, of which a General Conference of Oil Industry Representatives has voiced approval. The industry has accordingly recommended to the National Fire Protection Association that its model ordinance for the regulation of oil storage within corporate limits be revised to include such provisions for fire-bank design. The oil industry is obviously very appreciative of this fine piece of research work by Standard Oil Company of California, and by Mr. Hall in particular.

RALPH J. REED,* M. AM. SOC. C. E. (by letter).—The paper describes a practical and constructive piece of research which is of great and immediate value not only to the petroleum industry, but also to safety, fire prevention, and insurance interests. The studies made and the conclusions drawn form the groundwork for the proper and economic design for permanent fire-wall protection of containers in which crude or fuel oil is stored. They are particularly useful in outlining means for modifying existing protective structures either permanently, or temporarily in the event of fire, so as greatly to increase their effectiveness against boil-overs.

Well constructed oil storage works develop few leaks that must be retained by secondary structures; the careful operation of tanks and reservoirs results in few spills; and, where proper principles of design are followed, as the author states, one may practically disregard the possibility of the rupture or collapse of a full container. It follows that fire-wall protection is primarily required as a measure to prevent the spread of burning oil if a boil-over occurs during a fire involving crude or fuel oils.

Although some fire prevention authorities have insisted on greater fire-wall capacity, it has been the general custom to assume that a fire-wall structure so built as to retain the entire tankage which it is designed to protect will usually be adequate to prevent the spread of burning oil in case of fire. The sole criterion has been the quantity of fluid which the protective structure will safely hold, without regard to the form of barrier or its relative location with respect to the containers surrounded. Where sufficient gound has been available, low earthen embankments with side slopes varying from 1 on 1 to 1 on 2 are common fire-walls. The usual field practice of the oil industry has been to build such earthen walls to heights of 5 or 6 ft., and to place them from 75 to 100 ft. from the tank enclosed. In other locations in which tanks must be spaced more closely, either on account of operating conditions or because of the restricted areas available, vertical walls of masonry or concrete are used. Mr. Hall's experiments, a short series of which it was the writer's privilege to witness, show clearly the ineffective barrier to the progress of a boil-over wave of high velocity furnished by the ordinary earthen embankment or even by a plain vertical wall of moderate height. Experience with earthen embankments during tank fires, together with observations of some recent fires in large reservoirs, serves to emphasize this fact strongly and to point to the value of some device for destroying the energy of the wave.

* Chf. Engr., Union Oil Co. of California, Los Angeles, Calif.

All the types of reinforcement for ordinary earthen embankments on which the tests were run are valuable from a practical standpoint, although the greater effectiveness of the low auxiliary wall placed quite close to the container, as compared with a coping of the same height placed on the top of the standard embankment, and its relatively shorter length, would seem to make it most desirable. Such walls may be built of concrete, tile, or brick. It is a question whether lighter material than, say, $\frac{3}{16}$-in. steel plate, used as a coping, will successfully withstand the heat of burning oil, especially if repeated boil-overs occur; and in permanent installations even this material should be supported on posts, making a fairly expensive structure. Corrugated galvanized-iron sheets for temporary copings have been proven effective, but the writer questions their ability to resist the heat of successive boil-overs and is, therefore, of the opinion that their use should be confined to emergency installations as suggested by the author. Instead of steel plate, sheets of heavy asbestos board, properly supported, could be used.

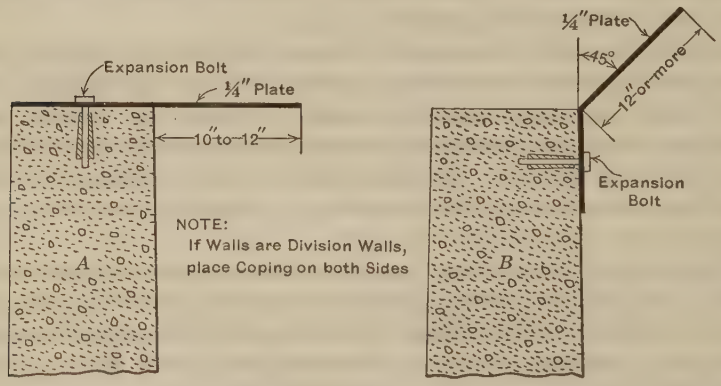

FIG. 20.—METAL COPING ATTACHED TO EXISTING FIRE-WALLS.

The striking value of even a relatively small coping on a vertical wall appeared in the few experiments witnessed by the writer. No fire-wall of this type should be built without incorporating a coping in its design. Existing fire-walls can be readily and quite inexpensively modified, it is believed, either by casting a concrete coping in place, or by the expedient of attaching a metal plate to the top of the wall, as shown in two forms, (*A*) and (*B*), Fig. 20.

H. H. HALL,* M. AM. SOC. C. E. (by letter).—The principles of fire-wall design developed in the paper are evidently proving of direct interest to the oil companies, several of which have carried the idea further and developed new methods for applying coping to their existing fire-walls. It is also interesting to note that in its recommendations to the National Fire Protection Association, the American Petroleum Institute has endorsed the coped type of wall.

* Chf. Engr., Standard Oil Co. (California), San Francisco, Calif.

Between January and November, 1925, the only oil fires in California of any magnitude have been in two large reservoirs; these were, incidentally, the only two reservoirs in the history of this industry on the Pacific Coast that have been fired by lightning. Although neither of these fires served to test the coped fire-wall idea completely, they both added to the knowledge of the general subject of fire-bank construction.

The first fire occurred at night in a reservoir about one-third full of heavy fuel oil. There was a substantial earth dike surrounding this structure, upon the top of which posts had been erected with the intention of establishing a permanent corrugated-iron coping somewhat similar to the metal coping on top of earth walls shown in Fig. 15. The coping had been delivered to the work, but none of it had as yet been put into place. After the fire started about 150 men placed 4 000 ft. of this coping in about 2 hours. At this same fire, another gang of about 150 men, with the aid of three tractors and fifteen teams, built about 3 000 ft. of temporary earth wall with metal coping. For this work the metal and posts had already been prepared; but otherwise everything had to be done after the fire started.

These figures serve to illustrate the speed which can reasonably be expected under stress of fire conditions, and at night. In a recent daylight fire drill, a gang of 18 men erected 150 lin. ft. of steel-plate coping on top of existing fire-walls in 10 min.

As a crude oil tank or reservoir always burns a number of hours before a boil-over occurs, and as there are generally a large number of men available for fire-fighting operations, it appears that there will practically always be ample time to place such temporary copings on fire-walls where they are needed. With this in view, the company with which the writer is connected is keeping on hand at various strategic locations a stock of plates, posts, tie-wires, and tools with which to erect emergency "steel fire-walls" as shown in Fig. 21. This plan obviates the heavy investment and maintenance charges that would be required for permanent copings on all walls, to which Mr. Reed refers.

Unfortunately for a study of coped fire-banks, the reservoir just mentioned did not boil over violently enough to test the coping. However, it did boil over; and an observation of the uniformity with which it spilled out practically all the way around the 1 600-ft. periphery suggests another form of fire-bank construction. This is the possibility, where reservoirs are concerned, of directing the boil-over to the least dangerous side of the container, by making the bank of the reservoir itself higher on the dangerous side. One reservoir embodying this principle was built four years ago; and there are now several reservoirs with auxiliary fire-banks built on top of their regular banks along the more dangerous side.

The other recent reservoir fire occurred in an isolated storage where there was practically no danger to other property. There was a substantial earth dike ranging from 8 to 16 ft. high, located about 200 ft. from the toe of the reservoir slope. The ground sloped gently toward the dike at a rate of about 5 ft. per 100 ft. This reservoir contained light crude oil, and boiled over with considerable violence. As there were no structures below it, no effort was made to erect a temporary coping; and this boil-over climbed the earth dike

with apparently little loss of energy—which evidence simply serves to confirm the test results and considerable previous experience with walls of this type.

Mr. Shoemaker's statement that "to be fully effective, the fire-wall must be placed one diameter from the shell of the tank", is in line with recommendations made by the Committee of the American Petroleum Institute, of which

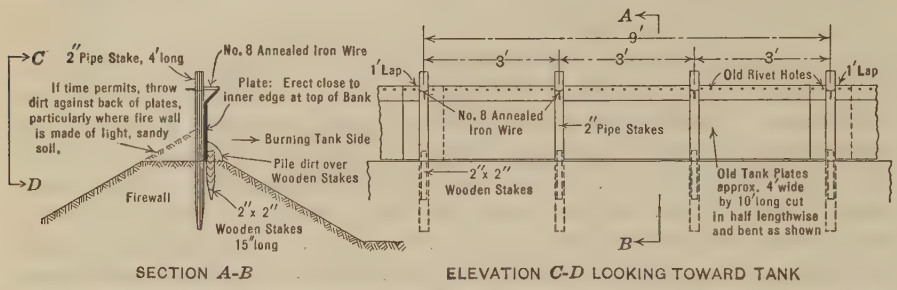

FIG. 21.—STEEL FIRE-WALL FOR REINFORCING FIRE-WALLS AROUND THAT PART OF A BURNING TANK OR RESERVOIR WHERE SPREAD OF BOIL-OVER WOULD BE ESPECIALLY DANGEROUS.

he was Chairman. This is the spacing which was considered ample to insure safety with all types of walls—particularly earthen dikes. In congested localities it is customary to use vertical concrete walls; and when such walls are provided with a substantial coping it will be noted from the comparison of Figs. 5 and 13 that at a distance of only 50 ft. from the tank they will stop substantially the same boil-over as at 90 or 100 ft. away—as would be required by strictly following the one diameter rule for large storage tanks. Hence, when space is limited, it would appear that almost as much reliance can be placed on heavily coped vertical walls located 50 ft. from the tank, as when such walls are farther away.

Paper No. 1576

ELEMENTS GOVERNING THE DEVELOPMENT OF HIGHWAY TRAFFIC*

By A. N. Johnson,† M. Am. Soc. C. E.

With Discussion by Messrs. Arthur W. Dean and Van Alen Harris.

Synopsis

The purpose of this paper is to discuss the amount of future traffic upon American highways and to compare this with the traffic capacity of a two-lane road.

In order to do this, it is necessary to project what the progress is to be in the future, and this is always fraught with many uncertainties. Even if the physical facts on which to base a prediction are known, social forces may not continue to act as in the past, and thus new conditions arise that affect vitally the results. If the facts are known, and the forces, both social and economic, do not sensibly change, then one may predict with considerable assurance what the future may be expected to bring forth.

The physical facts upon which highway traffic rests are the number of vehicles using the road in a given time, the road mileage made by these vehicles during some definite period, and the mileage of the system of highways upon which the traffic moves. If, through a considerable period of time, these quantities have persisted at concordant rates, then future values may be predicted. In the instance of highway use, the values thus found will be approximately true, provided the causes that create a desire for the use of the motor vehicle do not change. For the present purpose, it is assumed that such will be the case; that people will not tire of the motor vehicle as a form of recreation; that, due to further congestion, increased traffic will not become the means that will strangle itself. All that is favorable to the continuance of travel by highway is to be assumed. With these conditions imposed, it is useful to endeavor to see what the future holds in store for the highways.

* Presented at the meeting of the Highway Division, New York, N. Y., January 22, 1925.
† Dean, Eng. Coll., Univ. of Maryland, College Park, Md.

As has been indicated, the density of traffic over a system of roads depends on the vehicles using the system in a given time, together with the mileage made by these vehicles in a limited period, and the number of miles of highway in the system. The total number of motor vehicles is known. The average mileage per year per vehicle is variously estimated at 4 000 to 6 000 miles. Based on the gasoline consumption of the vehicles in certain localities, the average travel is about 5 000 miles per year. For the present purpose, the larger figure of 6 000 miles per year will be used.

There are in use (1924) approximately 18 000 000 motor vehicles, which would yield, on the assumption noted, a total annual traffic of 108 000 000 000 vehicle-miles, or an average daily traffic of nearly 300 000 000 vehicle-miles. This traffic, as every one knows, is far from evenly distributed over the approximately 2 500 000 miles of highways throughout the country. The bulk of the traffic is confined to a comparatively small fraction of the total road mileage.

It is a fact that few State highway systems, as at present developed, exceed 10% of the total road mileage of the State. For this discussion, it will be assumed that 75% of all highway traffic is carried on 10% of the highways. From these figures it is found that there is imposed on the main road systems an average daily traffic of 900 vehicles per mile.

Since 1917, under the direction of John N. Mackall, Chairman and Chief Engineer of the State Roads Commission of Maryland, traffic counts have been made at regular intervals at approximately 200 counting stations on the State Highway System, which comprises very nearly 10% of the total road mileage. From these traffic counts there has been compiled the average number of vehicles per mile per day throughout each year since 1917.

TABLE 1.—Comparison of Traffic Density as Computed from Motor-Vehicle Registration, Applying 75% of the Traffic to 10% of the Total Road Mileage of the United States, with the Traffic Density on the State Road System of Maryland, as Found from Actual Traffic Counts.

Year.	Average Number of Vehicles Through the Year per Mile per Day.	
	As computed for the United States.	As counted on Maryland State Road System.
1917	250	258
1918	300	277
1919	375	355
1920	450	439
1921	500	537
1922	600	579
1923	740	726
1924	900	818

In Table 1 the results thus obtained from actual traffic counts are compared with the amount of traffic as computed from motor-vehicle registration as previously outlined. It is seen from an examination of this table that the computed results are not widely divergent from those obtained from actual traffic

counts and, at least, establish the fact that the amount of highway traffic is a linear function of motor-vehicle registration.

May limits be set to this highway traffic? May a point be reached where the increase in traffic would be at the same rate as the comparatively slow increase in population? As the number of motor vehicles is a prime factor in this calculation, an answer may be found if a study is made of the motor-vehicle registration curve.

It is logical to assume that eventually the limiting number of motor vehicles per population will be reached, and when such a point is reached, the rate of increase of the motor-vehicle curve will be equal to that for the population curve.

In Fig. 1 the motor-vehicle registration curve is shown, based on data furnished by the U. S. Bureau of Public Roads, as published by the National Automobile Chamber of Commerce. Likewise on this diagram is the population curve. These curves have been platted on a semi-logarithmic scale; thus, the same rates of increase for each curve will exist at those points at which the curves are parallel. When the motor-vehicle registration curve becomes parallel with the population curve, the saturation point in the market for motor vehicles has been reached. When does this occur?

To assist in projecting the motor-vehicle registration curve beyond the current year, the number of persons per automobile is perhaps the most direct method of arriving at an answer to this question.

In Fig. 2 a curve has been platted that shows the number of persons per motor vehicle for the past few years. It is noted that the number of persons per automobile in 1919 was 14; in 1924, 6.2. In California, in 1923, the number of automobiles per person, according to statistics published by the National Automobile Chamber of Commerce, reached 3, and in Iowa, 4, ranging from these values to 19 persons per motor vehicle in Alabama, the average for the United States for that year being 7.4. It is difficult to imagine that an average of less than 4 persons per automobile will be reached. A continuation of the curve in Fig. 2 indicates that probably not earlier than 1926, and more likely about 1928, this point may be reached. On this latter assumption, the registration curve in Fig. 1 has been drawn, indicating a registration in 1928 of 29 000 000 motor vehicles. After that date, the rate of increase is shown as directly proportional to the increase in population. It is to be kept in mind that the assumption that has been made is based on a continuation of the desire to use motor vehicles that exist to-day; and as it is the intention to outline maximum conditions it is not necessary to consider what may happen from causes that would tend to reduce the amount of traffic.

An estimate of the average daily traffic to be expected by 1928, from the figures just given, may be made on a basis of calculation similar to that given previously, that is, concentrating 75% of the traffic on 10% of the road mileage, which gives an average daily traffic of 1 500 motor vehicles per mile.

The mileage of improved roads is constantly increasing, many sections of roads now traveled by a comparatively small number of vehicles will experi-

ence, when improved, an increase in traffic. This traffic will have been drawn away from those roads now included in the 10%, that is, there will be a

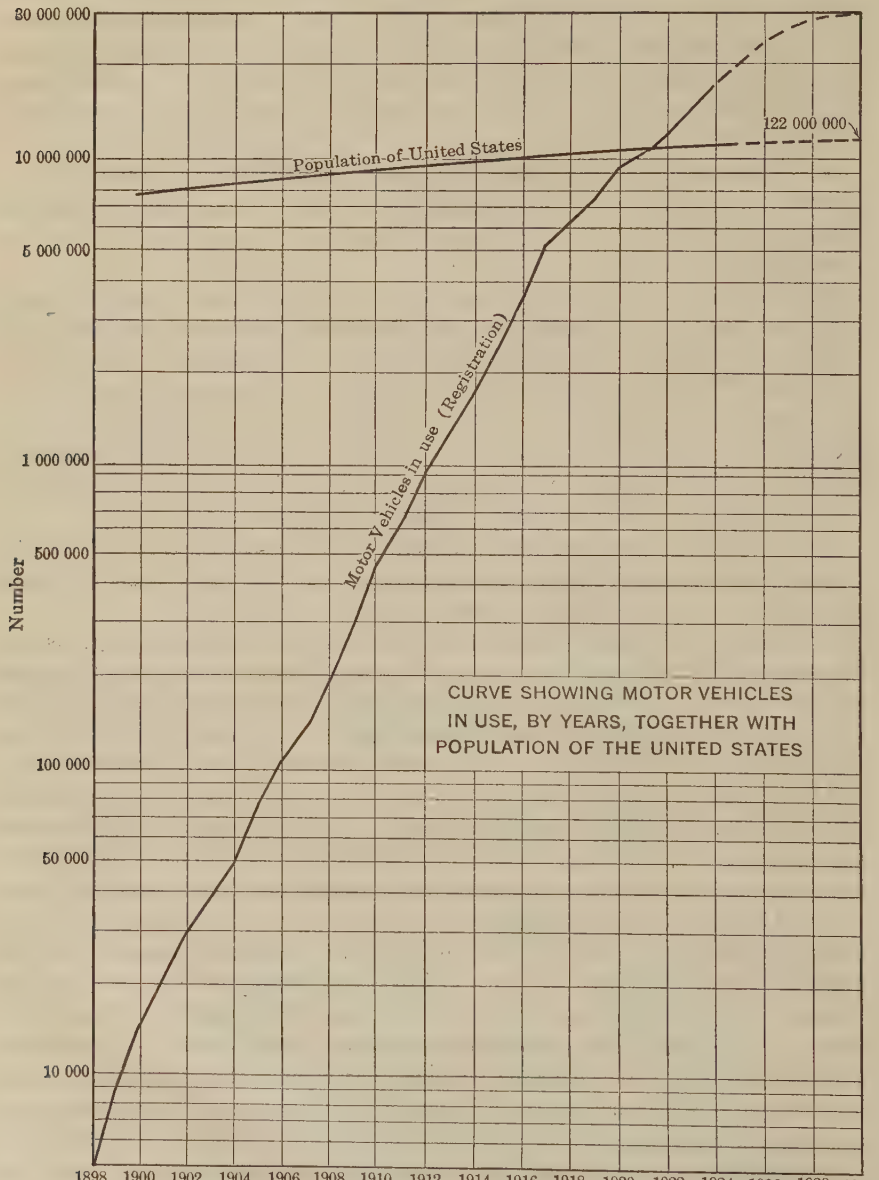

FIG. 1.

tendency to spread traffic over a larger proportion of the road mileage, all of which should have a tendency to reduce the density of traffic from the figure calculated—1 500 vehicles per day per mile.

From all the factors involved, and from the estimates made from these factors, it would seem to be safe to state that the present State highway systems, averaging about 10% of the total mileage, need not expect to be called on to carry in excess of an average daily traffic of 1 500 vehicles per mile. Every one can recall many evidences of traffic congestion and find it difficult to believe that much more traffic can be handled. This undoubtedly is true of some sections of certain highways where traffic concentrates. These particular sections of roads do carry nearly their capacity and frequently are taxed much beyond it; but the mileage of these sections of highways, so congested, forms only a small fraction of the total mileage of State highway systems.

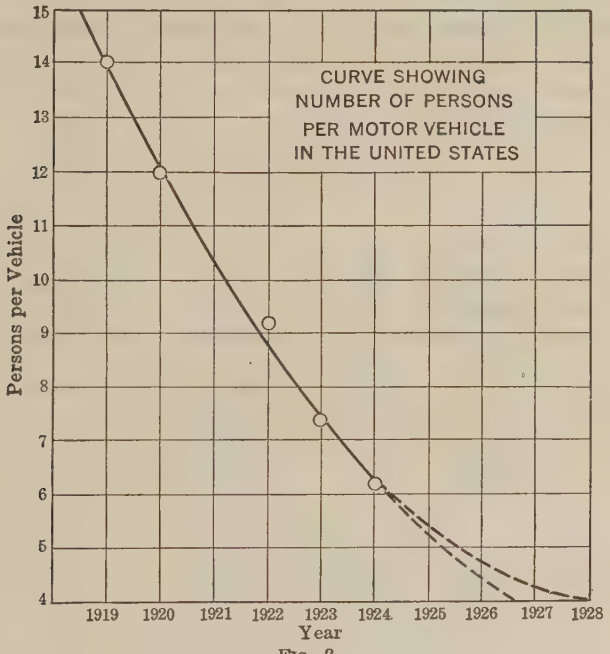

FIG. 2.

It is profitable, therefore, to make some comparison of the ultimate capacity of highways for the widths generally built at present with what has been set as the limit that may not be much exceeded for many years to come. The majority of highways on State highway systems provide for two lanes of traffic, and the traffic capacity of a two-lane road can be closely ascertained.

First, consider the question of the number of vehicles that may pass a given point in a single file, or what may be designated as the total discharge of a single lane of traffic. It is evident that this number is dependent on the velocity and the spacing or intervals between the vehicles; the vehicles to be considered as practically of a fixed length, which, for the present purpose, may be taken as 15 ft. Expressing the velocity, in miles per hour, as V,

and the clear distance between vehicles, in feet, as C, the total number of vehicles that will pass a given point in 1 hour is given by the relation:

$$N = \frac{5\ 280\ V}{15 + C}$$

in which, 15 represents the average length, in feet.

It is known from observation that as the velocity of the vehicles increases, the spacing is varied. Whether this variation is directly as the velocity, or some other function of the velocity, is difficult to determine with any precision. There is some evidence, however, to indicate that the spacing between the vehicles varies approximately as the square of the velocity.

During special rush periods on the Washington-Baltimore Road, groups of vehicles moving 10 to 15 miles per hour, frequently were spaced as close as 15 ft., and other groups moving 25 to 30 miles per hour maintained an average spacing of 50 to 60 ft. Assuming that the average length of a vehicle is 15 ft., and that the clearance varies as the square of the velocity, the number of vehicles discharged per hour would be:

$$N = \frac{5\ 280\ V}{15 + \frac{V^2}{15}}$$

If the first differential of this equation is equated to zero, it is found that N becomes a maximum when $V = 15$, that is, the interesting result is obtained that, if vehicles are spaced according to the square of the velocity, the maximum vehicle discharge will occur at 15 miles per hour, which, for a single line of traffic, equals 2 640 vehicles per hour.

The traffic capacity of a two-track highway was observed at a number of different points on the Washington-Baltimore Road on different days during a special rush of traffic on the occasion of the Laurel Races in October, 1924. Vehicles were counted at 5-min. and sometimes 10-min. intervals, through the

peak of the traffic. Whenever the road became congested, a note was made. It was considered to be congested when a faster moving vehicle could not conveniently pass a slower one. As typical of these records that made on October 25, 1924, is given in Table 2.

This count began at 4:30 P. M., and the lowest number of vehicles recorded was at the rate of 420 per hour, at which time traffic was about evenly divided in each direction. No inconvenience was noted, that is, traffic in either direction could maintain its speed of about 30 miles per hour, and was not held back by the occasional slower moving trucks, there being ample opportunity to pass. This condition prevailed until about 5:10 P. M., when it was observed that the road began to be congested. From the stream of traffic north, which was moving at an average speed of 25 to 30 miles per hour, vehicles could not turn out readily and pass a slower moving vehicle in front. This condition occurred when the traffic was between 800 and 1 000 vehicles per hour.

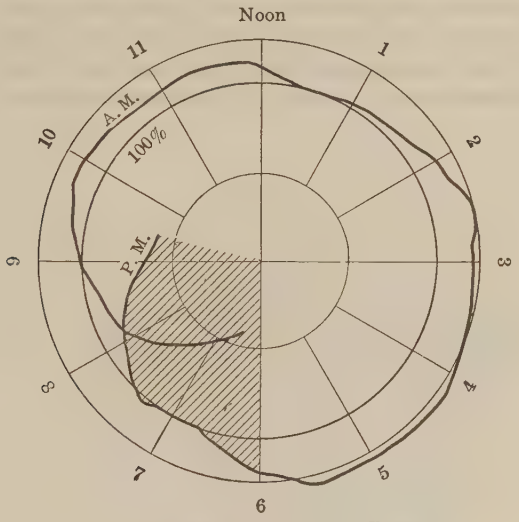

FIG. 3.—HOURLY VARIATION OF TRAFFIC.

It was noted that for a traffic of 1 368 vehicles per hour, of which approximately 90% were moving in one direction, the road was uncomfortably crowded. On another occasion when the traffic reached a rate of 1 296 vehicles per hour, the same notation was made, but, at 1 000 vehicles or less, this crowded condition was not recorded. It should be stated that the observations were made by a number of recorders.

At a speed of 30 miles per hour, based on the formula as previously stated, the distance between the vehicles varying as the square of the velocity, the number of vehicles passing in a single line per hour would be 2 100. The greatest number observed was 1 500, the average speed being noted as 30 miles per hour. Therefore, the actual spacing between the vehicles (185 ft.) was considerably greater than that provided by the formula which assumes the

spacing to vary as the square of the velocity, in which case vehicles would have a clearance of 60 ft. While the spacing was not uniform, yet the minimum clearance, as observed, varied from 50 to 60 ft.

From these conditions, the conclusion is reached that a two-lane road may carry traffic as great as 1 000 vehicles per hour without inconvenience to mixed traffic, the faster traffic having opportunity to overtake and pass the slower moving vehicles; and that for occasional peak traffic it will discharge readily, with traffic moving at an average speed of 25 miles per hour, at least to 1 600 vehicles per hour.

The next question is, what may be an average daily traffic if the recurrent high traffic load is not to exceed 1 000 vehicles per hour. This involves the diurnal variation of traffic. From results of various traffic studies, traffic in the mid-forenoon and late afternoon is 30 to 50% more than the average hourly traffic for the day. (See Fig. 3, which shows hourly variation of traffic.* The hourly average is shown as 100 per cent.) Thus, if 1 000 vehicles are to represent the recurrent daily peak traffic, the average hourly traffic should be taken at approximately 600 to 700 vehicles. For a 12-hour day, this would give an average daily traffic of 7 200 vehicles, which can be accommodated on a two-track road without congestion.

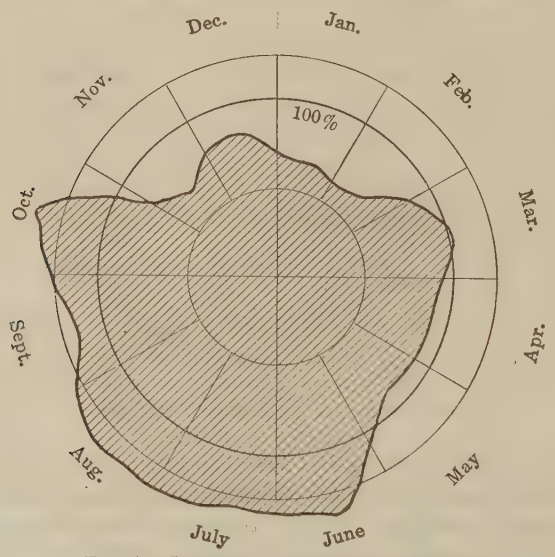

FIG. 4.—SEASONAL VARIATION OF TRAFFIC NEAR BALTIMORE, MD.

In order to determine the average daily traffic that may be maintained throughout the year, the seasonal variation of traffic must be studied. In the vicinity of Baltimore, which is perhaps illustrative of many sections, it is found that the average daily traffic, during the period from June through October, is about three-fourths greater than the average daily traffic for the

* Adapted from data on page 136 of California Highway System by the U. S. Bureau of Public Roads, 1920.

year. (See Fig. 4, which shows the seasonal variation of traffic near Baltimore, platted as percentage of daily average, shown as 100%, for 1917, 1918, 1919, and 1920.) If 7 200 vehicles per day is to represent the high seasonal average, then the yearly average should be taken at 4 000 vehicles per day, that is, there may be throughout the year an average daily traffic of 4 000 vehicles per day without causing congestion on a two-track road, allowance being made for the general increase in traffic due to seasonal variation and for the normal increase due to hourly variation throughout the day.

It was previously concluded that the largest probable expansion that may be reasonably expected in motor traffic, assuming 75% of the total traffic to be placed on only 10% of the roads, is an average daily traffic of 1 500 vehicles per mile, which is a little more than one-third the capacity of a two-track road.

With the highway systems built two lanes wide, supplemented by an increasing mileage of improved side roads, as well as extensions to the State roads themselves, it is not reasonable to expect that any general congestion of traffic will occur for many years to come. Congestion, however, will continue increasingly to occur at certain points where traffic tends to concentrate, until the forces which attract traffic to these centers cease to act. It may well be that the very congestion itself will cause such a point to be no longer a center of attraction. The traffic will stifle the very thing that attracts it. This is happening and will happen again unless means can be found to prevent continued congestion by additional roads, wider roads and streets, the dispersion of certain business activities, and, in general, the providing of a greater area for the traffic to be accommodated.

On the whole, however, engineers are proceeding wisely and sufficiently in the design of the larger proportion of the mileage of improved roads if a two-lane width is provided.

DISCUSSION

ARTHUR W. DEAN,* M. AM. SOC. C. E.—The prime origin of the extensive expansion of highways and the increase of highway traffic is the development of the internal combustion engine, just as the development of railroads and street railways in the Nineteenth Century originated with the improvement of the steam engine and the electric motor.

An outstanding factor of development in the United States, and one that is usually overlooked, is the general prosperity and aspiration of the people as a whole.

As in the past, various other elements will affect or govern the development of highways and the traffic over them, and some of these elements, although possibly mentioned by other writers, are so applicable that they will bear repetition:

1.—The gradual increase in efficiency and decrease in cost of motor vehicles leads directly to an increased use of such vehicles for the transportation of freight on what are commonly termed short hauls, and also toward an increase in the economical hauling distances.

2.—As the use and improvement of the motor vehicle progresses, the railway and railroad lines that are now being used mainly for short hauls may be outrivaled and their use discontinued, thereby increasing highway traffic.

3.—Many industries are now located at points somewhat remote from rail transportation lines, yet not so far from sources of raw material or from markets but that with improved highways and improved motor vehicles the highways may be profitably used for hauling their products. Such industries do and will tend to increase highway traffic.

4.—Opportunities exist for industrial and farming development in innumerable localities remote from transportation lines. Highway transportation will lead to development of the resources of these localities and, in turn, will re-act to increase further highway traffic.

5.—Passenger transportation by means of busses is increasing rapidly. Already there are several bus lines making regular daily trips between cities 100 miles apart, and many with hourly schedules between nearer points.

6.—There is always the inherent desire of the dwellers in congested areas to reach and enjoy the open country and for dwellers in the country to reach and enjoy the city scenes and activities. The average person enjoys a trip anywhere away from his own usual environment; there is also the professional man, the business man, and the artisan, who enjoy using, or may frequently of necessity use, the motor vehicle in preference to the old form of public or private conveyance. All these are large factors tending to increase highway traffic.

All these elements affect the development of highway traffic, but in order that such development may continue in healthy progress, the nations and subdivisions thereof must enact uniform and consistent laws and ordinances

* Chf. Engr., Div. of Highways, Dept. of Public Works, Boston, Mass.

of permissions and prohibitions, particularly as related to dimensions and speed of vehicles.

VAN ALEN HARRIS,* M. AM. SOC. C. E.—The viaducts across Biscayne Bay between Miami and Miami Beach, Fla., are illustrations of traffic saturation. The distance across the Bay is 3 miles, of which the larger part is a causeway with plenty of room for a very dense traffic. At each end of the causeway is a viaduct 2 000 ft. long and 20 ft. wide between curbs, allowing only one line of traffic in each direction. The speed limit is 25 miles per hour, with no passing of cars going in the same direction on the viaducts.

Miami Beach, with a building program of $4 000 000 per year, is a high-class residential section, and also the ocean bathing resort of Miami. Practically all labor working at Miami Beach comes from Miami across these viaducts and causeway. This flow of workmen returns to Miami between 4:00 and 6:00 P. M., which is the same time that the bathers return to Miami, with the consequent peak traffic between these hours.

In the summer of 1924, that is, out of the tourist season, 8 400 automobiles and trucks were counted crossing in 1 day, and between 1 200 and 1 300 in 1 hour, at the peak of the traffic, of which about 85% was going in one direction. No more could have passed, as there was a steady stream of cars which were urged to go as fast as possible, but, although the speed limit is 25 miles per hour, the average speed during the congestion was about 18 miles per hour. It may be assumed, therefore, that about 1 100 cars in each direction is the limit of a 20-ft. road under the most favorable conditions.

Paper No. 1577

THE EFFECT OF MOISTURE ON CONCRETE*

By W. K. Hatt,† M. Am. Soc. C. E.

With Discussion by Messrs. A. T. Goldbeck, G. E. P. Smith, and W. K. Hatt.

Synopsis

This paper reports investigations conducted by the Engineering Experiment Station of Purdue University in co-operation with the U. S. Bureau of Public Roads, and reviews the literature on the measurement of volume changes in Portland cements and concretes.

The primary purpose of the investigations was to measure the maximum warping and surface deformations produced in a concrete road slab as a result of a non-uniform distribution of moisture, to give a basis for estimating possible initial stresses. The tests also yield data of expansion and contraction of concrete, useful in the design of concrete structures.

The investigation was divided into two sections, namely: (1) Observations on a concrete road slab, 7 in. thick, 18 ft. wide, and 25 ft. long, resting on a porous sub-grade, covered with a tent and housed in a shed to control the distribution of moisture and the effects of temperature; (2) tests of strength and length changes of small beam units, some partly and some uniformly saturated.

Slab While Drying.—After curing under water the slab was dried by circulating air both above the slab and through the sub-grade. The more rapid drying of the top surface warped the slab to a maximum upward deflection of 0.12 in. at the corners and 0.04 in. at the unbroken edge during a period of 40 days, after which time upward movement ceased, the shortening of the diagonal being 0.0075 per cent. After 3 months of further drying, the slab had become approximately uniformly dry throughout its depth and substantially level, with a diagonal shortening of 0.0210 per cent.

* Presented at the meeting of the Highway Division, New York, N. Y., January 22, 1925.

† Prof. of Civ. Eng., School of Civ. Eng., Purdue Univ., Lafayette, Ind.

Slab Saturated on the Bottom.—In order to saturate the bottom of the slab, water was then introduced to the level of the top of the gravel sub-grade. During 110 days of saturation the slab again warped upward 0.20 in. at the corners and 0.066 in. at the unbroken edge. Simultaneously, a diagonal shortening of 0.0070% took place in the top face of the slab, of which 46% occurred in 2 hours and nearly all in 2 days. The shortening was caused by the expansive force of the saturated lower part of the slab, and occurred without a change in moisture content or temperature of the top layers. Assuming an elastic condition and a modulus of elasticity of 5 000 000 lb. per sq. in., a compressive stress of 350 lb. per sq. in. in the top is indicated. The level of the water was finally raised, but the concrete at the bottom apparently had become impervious and no further warping occurred. Then the surface was covered with saturated burlap to simulate the effect of prolonged rain.

Daily changes in the temperature of the slab resulted in differential warpings, depending on the degree of saturation and the temperature gradient. A typical daily change in air temperature above the slab of 42° Fahr. resulted in a variation of 3° Fahr. from top to bottom of the slab. The accompanying downward deflection of the corner due to this warping was 0.023 in., and the expansion of the surface, 0.0015 per cent. The movements due to this warping may be compared to a deflection of 0.20 in. and a shortening of 0.0057% due to the saturated sub-grade.

Measurements of the extensibility of concrete surfaces were reported by the writer to the American Concrete Institute, in February, 1926. The unit extensibility of 1 : 2 : 3 concrete before microscopic fissures appear was 0.00010, and at the time of cracks visible to the naked eye, 0.00018. Wet concrete was more flexible than dry concrete.

Loading tests were made on the corner of the slab for three conditions of warping.

The Beams.—Tests were conducted on concrete beams 4 in. by 7 in. by 4 ft.; some were uniformly wet, some uniformly dry, and some warped by non-uniform moisture distribution. The transverse strength was determined for dry, saturated, and partly saturated beams.

Beams uniformly saturated had a strength ranging from 80 to 85% that of dry beams, the average value being 82.0 per cent. Compression tests of wet concrete cylinders exhibited a strength of 75 to 83% that of dry cylinders, the average being 79.0 per cent.

Certain beams, previously dried from 3 to 4 months, were warped by saturating one face. In so doing the dry face was compressed for a small depth of saturation, and extended for medium and for maximum saturation. (See Appendix I.)

The dry face was tested as the tension face in a transverse flexure test. The variations in transverse strength for these various moisture conditions have been expressed in percentage values, 100% representing the completely dried specimens. The beams having a low depth of saturation and a shortened dry face exhibited a strength of from 109 to 127%, or an average of 118%; for medium saturation and slight extension of the dry face, the strength varied from 83.6 to 96.5%, or an average of 88.7%; for maximum saturation and greater extension of the dry face the strength was 80.7 per cent.

When the wet face was broken in transverse flexure these values became 83.5, 71.3, and 76.6%, respectively.

Volume Changes of Cements and Concretes.—Measurements, begun 2 days after moulding, of the volume changes in specimens of several brands of neat cements varied greatly. Expansion in water during 10 days was from 0.03 to 0.056 per cent. Contraction in air during 90 days subsequent to immersion was from 0.052 to 0.142 per cent.

Gravel concrete, 1 : 2 : 3.5 (Cement F), expanded 0.005% during 40 days in water, and contracted 0.041% during 90 days in air and 0.050% during 30 days in an oven. Gravel concrete, 1 : 1.5 : 3 (Cements A and D), expanded 0.005% in water, and contracted 0.015% in air and 0.0225% in the oven during the same periods.

Introduction

The investigation of the changes of shape of a concrete road slab caused by unequal moisture distribution, together with subsidiary tests described in this paper, was suggested by A. T. Goldbeck, Assoc. M. Am. Soc. C. E., at that time Chief of the Division of Tests and Investigations, of the U. S. Bureau of Roads, as a part of a co-operative work between the Bureau, T. H. MacDonald, Chief, and the Engineering Experiment Station of Purdue University, Dean A. A. Potter, Director.

The tests were made at Purdue University under the supervision of the writer and Professor R. B. Crepps. Mr. A. C. Benkelman was in direct charge, assisted by Mr. E. Gustavsen, both of the Staff of the U. S. Bureau of Roads. Mr. R. E. Mills, of the Engineering Experiment Station of Purdue University, assisted from time to time. Special acknowledgment should be made of the painstaking care in observations and the devotion to the tedious program of measurements contributed by Mr. Benkelman.

In these studies the following matters were examined:

1.—The maximum distortion (including deflection and fiber deformations) produced in a concrete road slab 18 ft. wide, 25 ft. long, and 7 in. thick, by a non-uniform distribution of moisture.

2.—The effect of moisture changes on the modulus of rupture and compressive strength of concrete, determined by subsidiary tests on (1) beams, 4 in. by 7 in. by 4 ft., and (2) cylinders, 6 in. in diameter by 12 in. long.

3.—The volume changes in the concrete beam specimens due to exposure, including warping due to partial saturation.

The approximate number of observations involved in the entire study was:

Type.	Number.
Deformation	40 000
Deflection	3 000
Strength	600
Weight	1 000
Temperature	1 500

Note.—When the word "dry" is used in this paper, it refers to condition of hardened concrete and not to consistency of fresh concrete.

Description of the Test Slab

The one-course concrete slab was 7 in. thick, 18 ft. 0 in. wide, and 25 ft. 0 in. long, with a longitudinal doweled center joint. A sub-grade, consisting of a 4-in. layer of coarse gravel, was held in an impervious wooden sub-base, the sides of which extended above the surface of the slab. The slab was housed in a shed and further protected under a tent. (Figs. 1 and 2.) It was cast on September 12, 1923. The subsequent treatment was as follows: (1) Cured under water for thirty days, until October 12, 1923; (2) the water removed and the slab dried for 188 days, until May 28, 1924; (3) the sub-grade saturated for 108 days, until October 20, 1924; and (4) the top covered with wet burlap.

Materials

A mixture of two brands of standard Portland cements, A and D, was used in one half-section of the slab and a single brand, F, in the other. The results of the usual standard tests of the cements are given in Table 1.

TABLE 1.—Test of Cement.

* Different samples.

The aggregates were washed sand and gravel from the Western Indiana Sand and Gravel Company at Lafayette, Ind.

The results of the sieve analysis and miscellaneous tests of the aggregates are given in Table 2.

The coarse aggregate was separated into three sizes: Between the 2-in. and 1-in. screens; between the 1-in. and the ½-in. screens; and between the ½-in. and the ¼-in. screens. It was then recombined in such proportions as to give maximum density according to Fuller's maximum density curve. The consistency of the mix was checked by the slump-cone method. All materials, including water, were weighed for each batch.

The properties of the concrete are listed in Table 3.

Expansion and Contraction of Cements.—The changes in length of six brands of cement and the concrete made from certain of the brands were measured using Berry extensometers. The specimens were 2 by 2 by 24 in. for neat cement and 4 in. by 7 in. by 4 ft. 0 in. for concrete. Measurements

began two days after moulding with previous moist-chamber storage. The results are shown in Table 4 and in Figs. 3, 4, and 5. Since the preparation of the paper in December, 1924, the measurements of expansion and contraction have been continued, and the curves in Fig. 3 extended. It appears that the individual behavior of the several brands of cement is confined to the first period of approximately sixty days, after which the movements of the several brands are alike. Fig. 5 represents a sampling of the market, six months later than Fig. 3. It appears that the several brands of cement maintain their relative properties.

If the measurements had begun at the time the specimens were moulded, the comparisons might have been different. (See Appendix II.) A comparison of the basic water content and the voids in the cement paste at this basic water content would no doubt throw light on these differences in the changes of

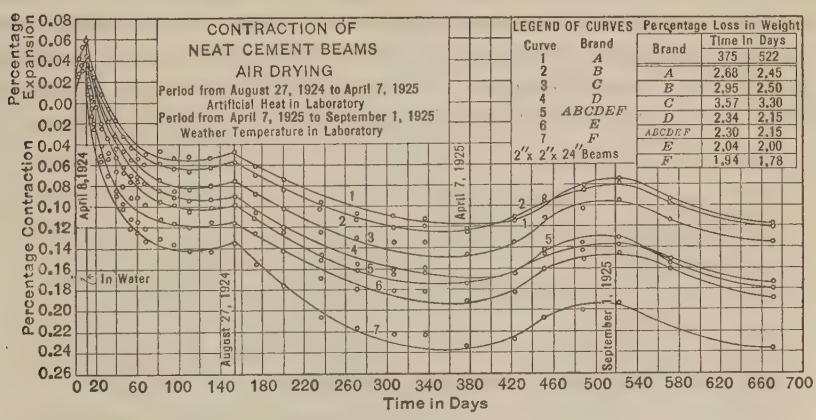

Fig. 3.

length, in the quantity of water required for standard consistency, and in the fineness or percentage retained on the 200-mesh screen as noted in Table 4. The basic water content has been defined by A. N. Talbot, Past-President, Am. Soc. C. E., as the percentage of water at which the voids are a minimum.

It appears that those cements which expand most in water, subsequently contract least in air. The neat cement prisms expanded in water nearly ten

times as much as the concrete beams; in air, they contracted nearly five times as much as the concrete.

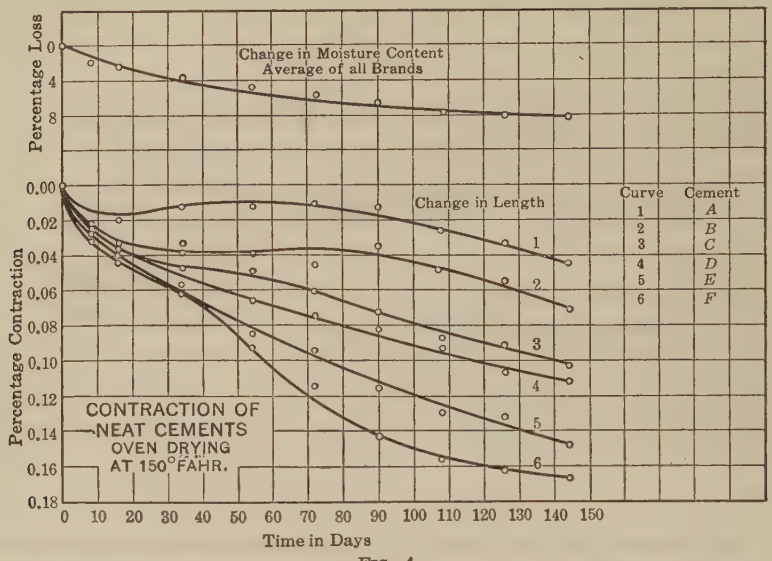

FIG. 4.

Expansion Due to Temperature.—The coefficient of temperature expansion of two concretes was measured, with the results shown in Fig. 6. The coefficient varies in amount depending on the temperature, ranging from 0.0000040 per 1° Fahr. to 0.0000065 at a temperature of 150° Fahr. The specimens were dried in an oven previous to testing. In Fig. 6 is shown the thermal coefficient of expansion of several concretes. The temperature of the concrete was obtained from blank beams in which were thermometer wells, consisting of

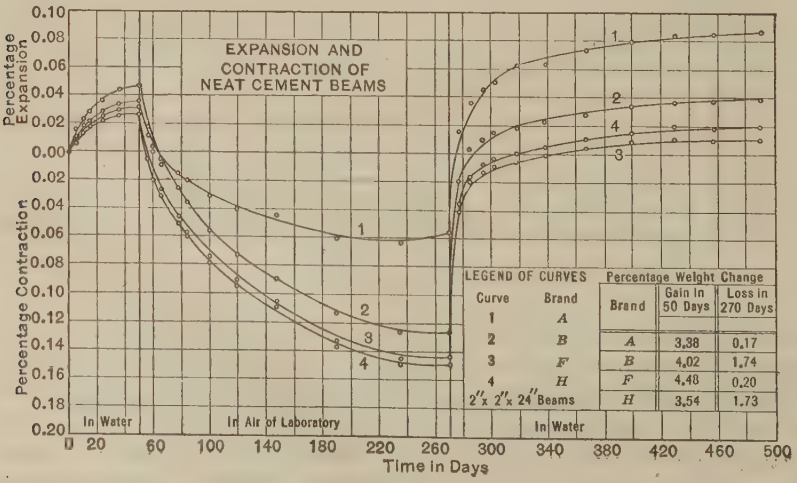

FIG. 5.

steel pipes filled with a light paraffin oil. The thermometers were graduated to one-fifth of a degree. Reading from the left, the chart covers: (1) Three beams, 6 in. by 8 in. by 4 ft. 0 in., 1 : 1.5 : 3 mix, age, 2 months, cured under wet burlap during 30 days, and dried in the oven at 150° Fahr. for 21 days. The beams were taken from the oven and readings taken at intervals of 20° Fahr. as the temperature dropped. Four cycles were read on as many days; (2) two beams, 7 in. by 4 in. by 4 ft. 0 in., 1 : 2 : 3 mix, age, 2 months, kept immersed in water the temperature of which was varied and held constant 2 hours before observation; (3) three beams, 4 in. by 7 in. by 4 ft. 0 in., 1 : 2 : 3.5 mix, age, 9 months, cured under wet burlap for 14 days, oven-dried for 1 month, and air-dried for 7½ months; the beams were moved from the warm laboratory air to the cold air of a shed; and (4) two beams, 4 in. by 6 in. by 4 ft. 0 in., 1 : 2 : 3 mix, age, 2 months, cured under wet burlap for 14 days, in air, 6 weeks.

These curves indicate that the variation of coefficient of thermal expansion varies with the temperature range under observation. The thermal coefficient of expansion for the several brands of cement tested neat was as given in Table 5.

7	0.0000085	0.0000085

Beams and Cylinders—Uniform Moisture

A series of tests, subsidiary to the road slab, on beam units and compressive cylinders has included a study of the following:

Length changes resulting from:

1.—Continuous immersion in water.
2.—Continuous exposure to air in the laboratory.
3.—Continuous exposure to weather.
4.—Oven drying at 150° Fahr.
5.—Immersion of oven-dried and air-dried specimens.

Transverse strength determinations as to:

1.—Decrease due to uniform saturation.
2.—Changes due to age and treatment.
3.—Effect of freezing temperatures on saturated and dry concrete.

Compressive strength tests for:

1.—Increase due to age and treatment on compressive strength.

The size of the beam specimens was 4 in. by 7 in. by 4 ft. 0 in.

In the initial series of tests concrete similar to that of the road slab was investigated, namely, a 1 : 1.5 : 3 mix, using Cements A and D. In a later series of tests, Cement F was used, the mix being 1 : 2 : 3.5.

Length Changes of Beams.—Measurements of changes in lengths of the beams due to moisture were begun two days after moulding. A 20-in. Berry strain-gauge, used in the measurements, was compared to a standard Invar steel bar, maintained at a constant temperature. Six gauge lines were set in each beam, three on the top and three on the bottom. The results are the average of measurements on at least four beams. Corrections for the influence of temperature were made from observations of the temperature of two auxiliary beams, the thermal coefficient of which was previously measured.

Figs. 7 and 8 show the percentage changes in moisture content and the corresponding change in unit length of the concrete. The 1 : 2 : 3.5 concrete, Cement F (Fig. 7), expanded 0.0050% after a continuous curing under saturated burlap for 40 days and contracted 0.0035% after 90 days in air. The 1 : 1.5 : 3 concrete, Cements A and D (Fig. 8), expanded 0.0050% after a similar curing for 40 days and contracted 0.015% after 90 days in air. Thus, considerable variation is evident in the degree of length change of the two concretes as affected by the character of the cement.

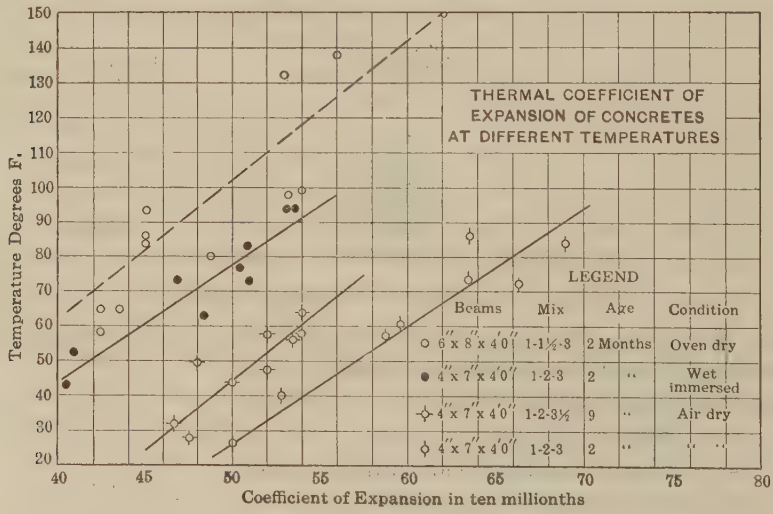

FIG. 6.

Additional beams of concrete, using Cement F, were exposed in the weather Changes in length and weight and the amount of rainfall were observed, as shown in Fig. 9. A maximum contraction of 0.033% occurred in 75 days. Beams of similar concrete exposed to the air of the laboratory for the same period of time contracted 0.033 per cent.

Tests at Purdue University in February, 1926, show the shrinkage of several aggregates in several mixes.

The beams were 4 in. by 7 in. by 4 ft., removed from the forms 3 days after pouring and cured under wet burlap for 14 days, following which they

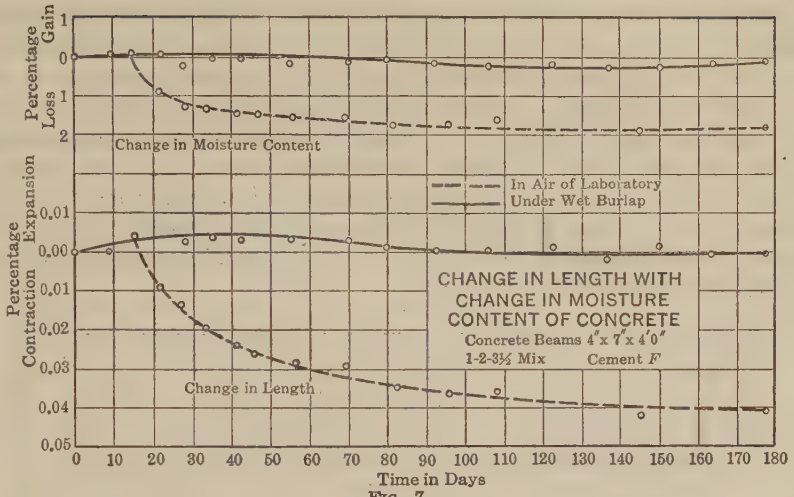

FIG. 7.

were exposed to the air of the laboratory. Corrections for temperatures varying by 5° were made. The aggregates were gravel, hard limestone, and slag. The fine aggregate was a well graded sand.

The contraction at the age of 80 days was, as follows:

	Contraction in percentage.
Neat cement	0.056
1 : 2 mortar	0.054

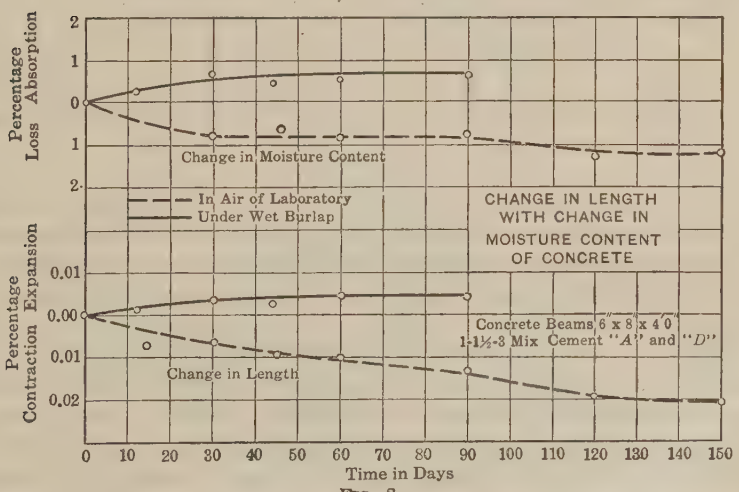

FIG. 8.

The average of the three aggregates shows the following contraction:

1 : 2 : 3	0.028
1 : 2.5 : 4	0.026
1 : 2.5 : 5	0.025
1 : 3 : 6	0.021

Transverse Strength.—The beams were tested (1) by loading at the third points, the span length being 42 in.; and (2) by loading them as cantilevers.

In the former case, the deformations of the top and bottom faces were measured by 10-in. Berry strain-gauges; in the latter, one end of the beam was fixed between the bed and the movable head of a testing machine and broken near the section of support by means of an attached lever arm 5 ft. in length. In this manner a number of sections of one beam may be broken consecutively. To load the testing machine shot was allowed to flow into a bucket. The halves of the beams broken under the third-point loading were also tested under cantilever loading.

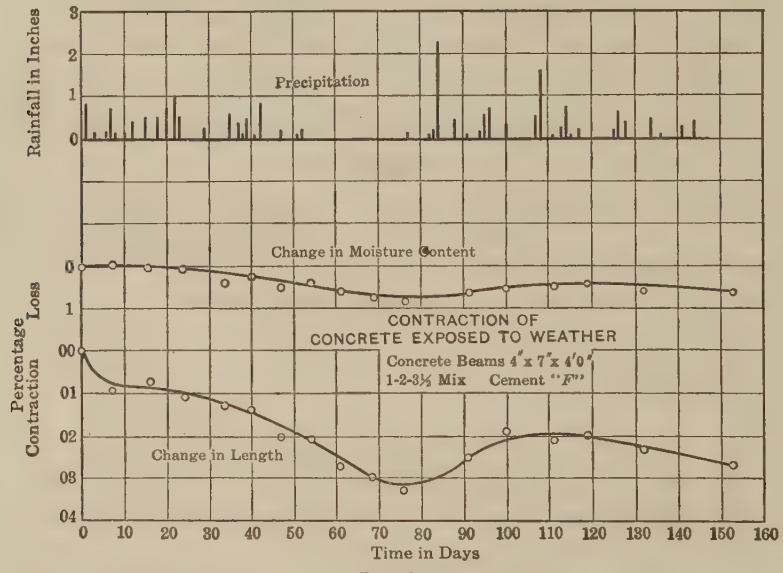

FIG. 9.

Fig. 10 shows the relative strength values of a series of tests on concrete beams made with Cements A and D. A 20% reduction results from saturation. An increase of approximately 100% in strength appears when saturated concrete is tested in a frozen condition. This is due to the strength of the ice. The percentage relation is based on air-dried concrete.

In Fig. 11 is shown the effect of age and moisture on transverse strength of beams. The specimens that were cured continuously under wet burlap and those air-dried, but subsequently saturated, contain approximately the same quantity of water by weight. The latter, however, are consistently 19% lower in strength on a direct basis than the former at an age of 90 days. All the specimens were made at the same time, and then exposed to varying conditions. Each plotted point in Fig. 11 represents the average of twelve tests.

No doubt the water is concentrated to some extent at the surface of the samples that are air-dried, but subsequently saturated. The appearance of the broken specimens, however, indicated uniform moisture distribution.

Compressive Strength.—Cylinders 6 in. in diameter by 12 in. long were capped with plaster of Paris and tested in compression. Deformations were measured to about one-half the ultimate strength by means of a ring com-

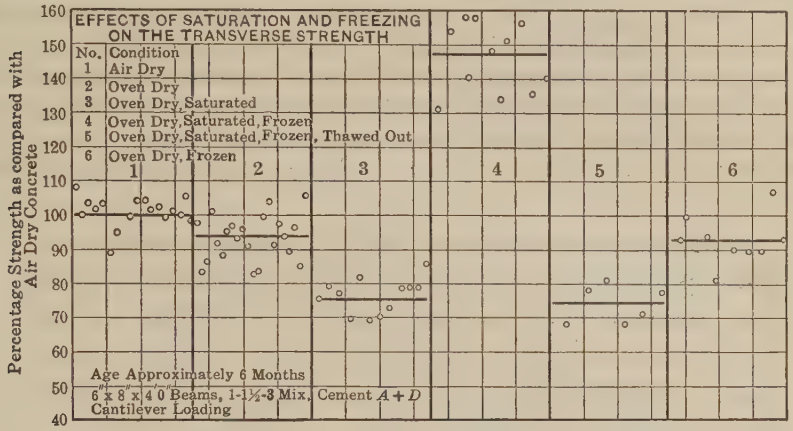

FIG. 10.

pressometer, with the results shown in Fig. 12, which checked the findings in the case of the beams. Each plotted point represents the average of three tests.

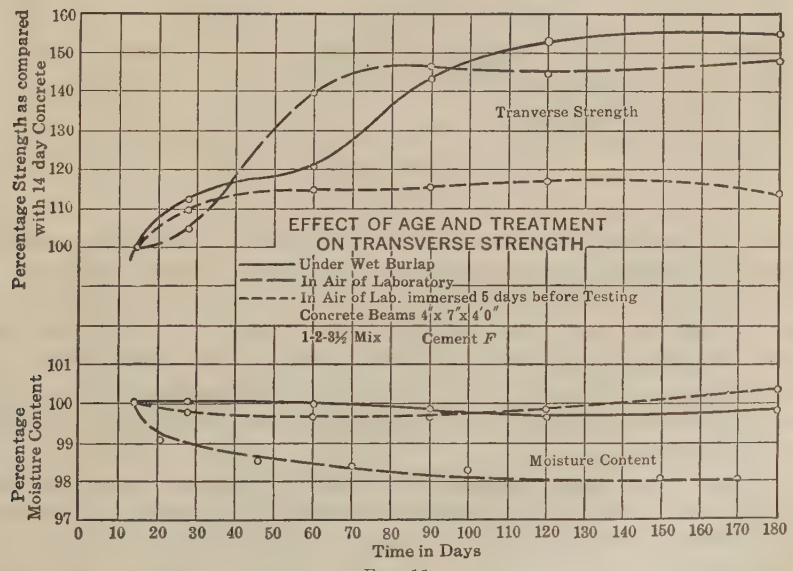

FIG. 11.

Aggregate failures occur with consistent regularity in the case of the air-dried or oven-dried specimens, likewise with specimens cured continuously under damp burlap; in the case of the saturated concrete, however, the failures are invariably due to bond between the mortar and the aggregate.

Results of Tests of Slab

Method of Tests.—By means of perforated pipes in the gravel fill and an air-pressure system, a dry sub-grade was finally obtained. Warm dry air was maintained above the slab in the tent enclosure. Water could also be introduced in the sub-grade when desired.

Previous to the construction of the slab, concrete bench-marks for the support of deflection beams were set 4 ft. 0 in. below the level of the ground. Rods extended upward from the bench-marks through pipes set in the sub-grade and slab. The slab and observation layout is shown in Fig. 1, and in Fig. 13.

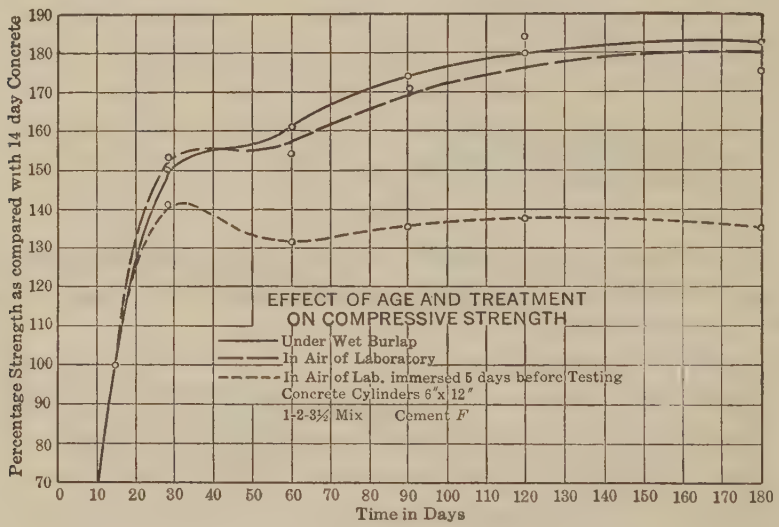

Fig. 12.

The deformation measurements were made with the 20-in. Berry strain-gauges. Deflections were measured with Ames dials reading to 0.001 in.

Non-Uniform Drying.—Following the curing period (immersion for 28 days) hot dry air was forced under the slab through the perforated pipes in the gravel fill by a pressure fan; simultaneously, a drying atmosphere was maintained above the slab in the tent enclosure. Observations of the subsequent deformations and deflections were taken at weekly intervals. (See Figs. 14, 15, 16, and 17.)

The more pronounced shrinkage occurring in the upper fibers was manifested by the fact that the edges and corners gradually curled up. A maximum uplift of 0.04 in. for the unbroken edges (at Point 2, Fig. 14), and 0.12 in. for the corners (at Point 1, Fig. 14), was attained at the end of 40 days. The subsequent return to a non-warped or uniformly dry condition required 5 months. A slight permanent distortion, as shown at Point 3, Fig. 15, representing the diagonal profile previous to the saturation of the sub-grade, is attributed to the more pronounced contraction of the richer or troweled surface than of the body of the slab. Observations were made of the longi-

tudinal, transverse, and diagonal deformations in the upper surface of the slab. An average of two corner diagonals is shown in Figs. 16 and 17.

All measurements of surface deformations of the slab were corrected for these changes in temperature which took place uniformly throughout the concrete. That is, while the readings of warping, caused by the moisture gradient in the slab, were always taken when the temperature was uniform throughout the depth of the slab, there might be a general drop in temperature between the readings of two successive weeks. In this case, the deformation readings on top of the slab were corrected for the temperature on the basis of a coefficient of expansion appropriate to the temperature of the concrete. (See Fig. 6.) Therefore, the deformations shown in Fig. 16 are net after the corrections have been applied.

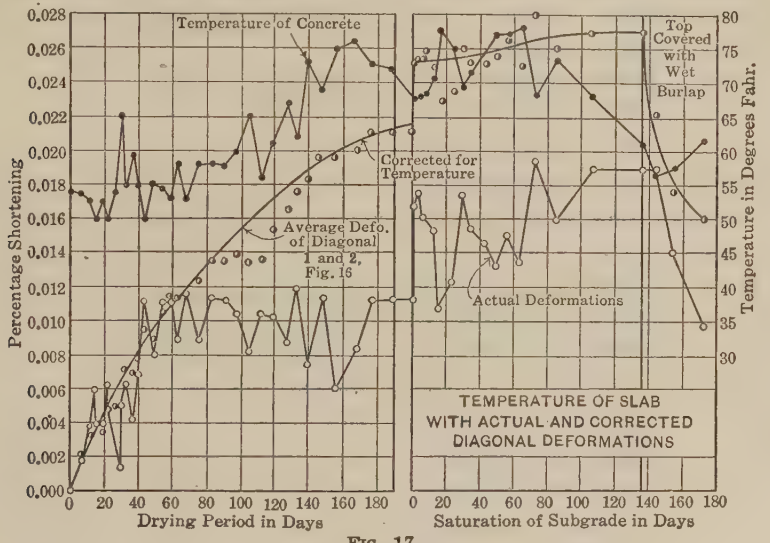

FIG. 17.

Fig. 17 shows the actual and the corrected deformations, together with the changes of temperature of the slab concrete (uniform throughout the depth of the concrete). It was not thought that the vertical deflections caused by the moisture gradient need be changed on account of these uniform changes.

The total diagonal contraction due to the moisture gradient between the condition of saturation (November 22, 1923) and that of completely dried concrete (May 28, 1924) was 0.021 per cent. This value, like all others, has been corrected for uniform temperature changes. Beams of 1 : 1.5 : 3 concrete contracted 0.020% in 160 days. The friction of the sub-grade apparently did not restrain these movements.

The fact that some of the points fall off the curve in Fig. 14 is attributed to a slight effect of temperature in the warping of the slab. In so far as possible, the observations were taken at times when the temperatures were uniform from the top to the bottom of the concrete.

Effect of Daily Variations of Temperature.—The effect of daily variations of temperature in the air above the slab (not the outdoor temperature) is shown in Fig. 18. A temperature rise of 40° Fahr. from 8:00 A. M. to 3:00 P. M.,

warped the corner downward 0.023 in., or 21.0% of the total warping (0.11 in.) at that period. The temperature of the concrete in relation to that of the air was as given in Table 6.

Non-Uniform Saturation.—Following the drying period, water was introduced into the gravel sub-base and maintained level with the lower surface of the slab. Differential expansion from bottom to top was again manifested in an immediate and continued gradual curling up of the edges and corners. A maximum distortion of 0.066 in. for the unbroken edges and 0.202 in. for the corners was attained at the end of 3 months. Typical results of the observations from June 2, 1924, the date of starting the saturation tests, until October, 1924, are shown in Figs. 14, 15, 16, and 17.

Subsequently after resaturating it the surface contracted diagonally 0.007% in 110 days; of this contraction, 46% took place in 2 hours and, approximately, 100% in 2 days.

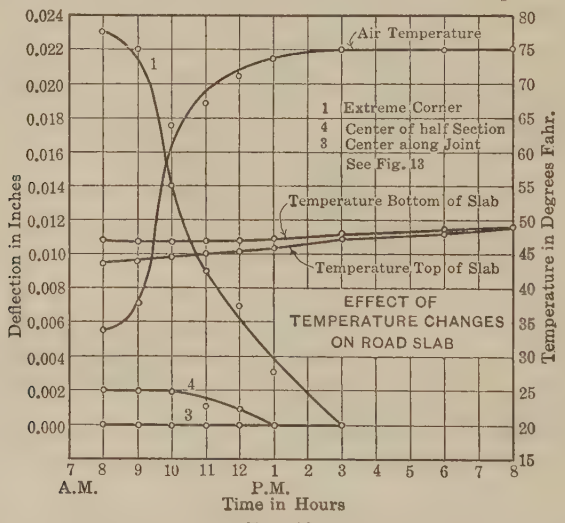

FIG. 18.

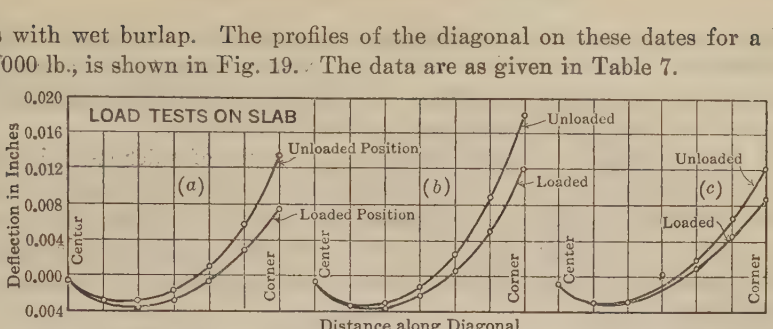
When the slab had reached a static condition with saturated sub-grade (on October 20, 1924), an attempt was made to expand the surface by applying saturated burlap. In 30 days the corner had dropped 0.060 in., to a deflection of 0.140 in.

TABLE 6.—TEMPERATURE VARIATIONS.

Time.	8:00 A.M.	3:00 P.M.	8:00 P.M.
Temperature of air, in degrees Fahrenheit	34	75	75
Temperature of top slab, in degrees Fahrenheit	44.0	47.5	49.0
Temperature of bottom slab, in degrees Fahrenheit	47.0	48	49.0

Load Tests on Slab.—Known loads were applied to one corner of the slab by jacking at three stages of the test: (*a*) On June 14, 1924, during the drying stage; (*b*) on September 23, 1924, during the saturation of the sub-grade; and (*c*) on November 14, 1924, when the top had been saturated 25

days with wet burlap. The profiles of the diagonal on these dates for a load of 3 000 lb., is shown in Fig. 19. The data are as given in Table 7.



Deflections of Corner Diagonal under Load of 3000 lb. at Corner

Figure	Condition	Date	Deformation along Corner Diag.	Stress from $S=\frac{MC}{I}$	Mod. Elas. in Tension
a	During Drying	June 14, '24	0.000037" per inch	185.0 lb. per sq. in.	5 000 000
b	Bottom Wet	July 23, '24	0.000035" " "	185.0 " " " "	5 300 000
c	Top Wet	Nov. 14, '24	0.000031" " "	185.0 " " " "	6 000 000

FIG. 19.

As the warping of the slab increased (see Fig. 19(*b*)), the point of support must have moved in, increasing the deflection. Curiously enough, the deflection of the slab under load when the top was wet was less than in either of the other two cases.

TABLE 7.—DEFLECTION OF SLAB DUE TO CORNER LOAD OF 3 000 LB.*

	a.	*b.*	*c.*
Corner level, in inches :			
Before load	+0.0181	+0.0183	+0.0124
With load	+0.0077	+0.0120	+0.0091
Deflection due to load	0.0054	0.0063	0.0033
Set due to load, after 5 min.	+0.008	+0.009	+0.008
Percentage of elongation under stress (in distance of 48 in. adjacent to the corner) :			
Diagonal	0.0037	0.0035	0.0031
Edges	0.0025	0.0023	0.0017

* Sign + indicates that the elevation is above the original level of the surface of the slab after casting.

Reversed Stresses on Saturated Mortar.—The fatigue limit on 1 : 2 mortar tested dry at an age of 6 to 12 months was approximately 55% of the once applied load, as reported* by Professor R. B. Crepps, of Purdue University. Similar beams, 18 months old, were also tested in the fatigue machine, while saturated, with the following results:

The saturated beams showed 89% of the static strength of the dry beams.

Beam No. 162 failed at 200 reversals under a load equal to 55% of the once applied load on saturated concrete; duration of test, ⅓ hour.

Beam No. 161 failed at 8 400 reversals at 50% load; duration of test, ½ day.

Beam No. 165 failed at 17 200 reversals of 50%; duration of test, 1¼ days.

Beam No. 164 failed at 71 700 reversals of 40%; duration of test, 5 days.

These tests are being continued. It would appear that a little less than 55% of the static strength of dry concrete should be the working strength of the concrete that has been saturated 8 days.

* *Proceedings*, Am. Soc. for Testing Materials, 1923.

Observations on a Concrete Stadium.—Gauge points are set at a number of locations both in the open deck and in the bank revetment of the new Ross-Ade Stadium of Purdue University. The changes of length consequent upon moisture and temperature variations are under observation.

A parapet wall, 6 in. thick, reinforced at center of thickness with 0.3% of reinforcement each way, is integral with a heavy foundation wall. A drop of air temperature of 38° Fahr. appeared as a drop of 28° Fahr. in the wall. The coefficient of thermal contraction was 0.00000725 in. per degree Fahrenheit at the top of the wall and 0.00000305 in. at the junction of the parapet wall with the base.

The movement across a fine crack in the middle of the 42-ft. length of this parapet wall was 0.000471 in. per degree Fahrenheit; and at the bottom across the crack, 0.0000717 in.

Under a drop of air temperature of 38° Fahr., the concrete in the open deck section of the stadium was 37° Fahr.; and the concrete of the revetment, 24° Fahr. The coefficient of thermal expansion of the open deck was 0.00000590 and that of the revetment, 0.00000492.

The effects of a rainfall, followed by a drop in temperature of 10° Fahr., balanced each other and no change of length was recorded in the deck, corresponding to a thermal coefficient of 0.0000050 and a swelling of 0.005 per cent.

The top of the parapet wall between winter and summer expanded with a coefficient of 0.00000595 for 1° Fahr., and from summer to February, 1926, it had contracted with a coefficient of 0.00000432. The difference between these coefficients is no doubt due to the moisture in the concrete during the winter weather. The average of the two coefficients is 0.00000513.

These same coefficients for the reinforced open deck are 0.00000346 and 0.00000236 respectively, or an average of 0.00000291, which no doubt is a measure of the restraint of the columns and surrounding structure.

The coefficients for the deck on the fill, that is, the revetment, are 0.00000547 and 0.00000267, or an average of 0.00000407, again an expression of constraint.

Conclusions and Application

As a result of the studies described in this paper and its appendices the writer has reached the following conclusions:

1.—The strength of concrete, like that of wood, varies with its moisture content. Although the law relating to moisture content and to strength was not determined throughout various ranges of moisture content, it appears that saturated concrete will have 80 to 85% the strength of dry concrete.

2.—The thermal coefficient of expansion of concrete varies with the temperature of the concrete and ranges from 0.0000040 at 65° to 0.0000060 at 140 degrees.

3.—Concrete expands when immersed in water and contracts on drying. The degree of change of length varies with the characteristics of the brand of cement, with the richness of the mix, with the size of specimen, and with the conditions of exposure. Measurements begun after the initial hardening of the cement show that concrete may expand 0.01% due to the absorption of moisture, and may contract 0.06% when exposed to dry air. These

changes continue. To these values should be added the changes in length during the initial setting of the cement.

4.—Concrete road slabs warp upward at the corners and at the edges when the surface becomes dry, and also when the bottom absorbs moisture from the sub-grade. Drying the top surface of the slab under observation deflected the corners upward 0.02 in. When the bottom of the slab was saturated from a water-filled sub-grade the upward corner deflection reached 0.20 in.

5.—This curling upward of the corners of the road slab presents a cantilever beam to the load of a passing truck. The results of the tests indicate the presence of an initial stress in the surface of the road slab arising from the warping.

6.—A combination of shrinkage from drying and from a fall in temperature will produce maximum shrinkage strains. A combination of a drop in temperature and a rainfall may retain the concrete at its previous length. The friction of a road slab on its sub-grade is an element favoring the production of cracks.

7.—To be durable, concrete structures should be designed for the least favorable conditions. Stresses arising from the effect of temperature and moisture as well as those due to dead and live loads should be considered.

8.—Without careful curing concrete masses will undergo excessive surface shrinkage against their rigid cores, thereby favoring surface cracks. Therefore, steel reinforcement should be placed near enough to the surface to withstand these shrinkage strains, and at the same time far enough below the surface to be protected against corrosion.

9.—The foreign experiments cited show the benefit of early and careful curing of concrete in reducing final shrinkage. The greater part of the shrinkage of mortar specimens took place in the first ten hours. These foreign experiments also show the greatly increased shrinkage of mortar mixed with an excess of water.

10.—Since the results of measurements of expansion vary with several factors, such as the size of specimen, the time of initial measurement, and the exposure, the method of such tests should be standardized.

The writer believes that the following are the requirements for concrete structures exposed to the weather:

(*a*) A Portland cement of normal volume constancy and a clean, well graded aggregate.

(*b*) An impervious concrete of proportions not less than 1 : 2 : 4.

(*c*) A time of mixing of not less than 1 min. and preferably 1½ min. for the production of uniform concrete.

(*d*) A concrete mixed with a minimum quantity of water appropriate to the work at hand.

(*e*) Careful slicing of this dry concrete against the face of the forms so that the reinforcing steel may not be exposed nor the surface require patching.

(*f*) Early curing begun just after the initial set and continued for a time depending on local conditions.

(*g*) Design of reinforcing steel and contraction or expansion joints to prevent cracking and the entrance of water.

APPENDIX I

Study of Warped Beams

Description of Tests.—The beam specimens were dried to constant weight; some were then entirely immersed in water and others immersed to only a fraction of their depth. The changes in weight, length, and strength were determined for the different conditions. Five separate series of such experiments were conducted, varying the proportions of the mix, the brand of cement, the extent and nature of drying, and the depth of partial saturation. The results are shown in Table 8.

Results of Tests.—By reference to Table 8, a comparison of beams uniformly saturated shows that the expansion in water varies from 0.014 to 0.021%, with an average of 0.018 per cent. These beams were immersed for 5 days subsequent to the initial drying. The 1 : 2 : 3.5 concrete made with Cement F when air-dried for 2½ months contracted 0.041 per cent.

The 1 : 1.5 : 3 concrete made with Cements A and D mixed, after conditioning by 30 days, curing under wet burlap followed by complete oven-drying, contracted 0.022 per cent.

The reduction in strength from completely dried concrete to uniformly saturated concrete in the five cases ranges from 11.7 to 22.2%, an average of 15.4 per cent.

Certain beams were warped by saturation from the bottom upward to increasing heights (see Table 8), as determined by visual observations of the broken beams and by weighing.

Contractions from 0.0016 to 0.0065% were developed at the dry face, and expansions from 0.015 to 0.032% at the wet face, of the warped beams. When these warped beams were broken with the contracted dry side in tension, an increase from 9.5 to 27.0% in strength over the entirely dry beam was indicated, depending on the amount of initial contraction.

When saturation had proceeded to a greater height in the beams (approximately 2 in. from the top), the area of dry concrete became too small to hold back the expansion of the wet area, and, consequently, the dry face was actually elongated by the force of the expanding face. When the expanded dry face was tested in tension, the beams were only 80.7 to 96.5% as strong as the uniformly dry beams; when turned with the wet side in tension, the percentage was 71.3 to 83.5. The complete data are given in Table 8.

The writer accounts for this increase in strength of warped dry faces when they have been shortened and the decrease in strength when they have been lengthened due to the absorption of moisture on the opposite face by the presence of an initial compression in the former and of an initial tension in the latter case. However, an analysis of moduli of elasticity and the deformations of the top and bottom face of the beams, tested under the one-third point loading, fails to show any substantial difference between the extensibility, at rupture or 50% of rupture, of the beams with the dry face either shortened or lengthened by warping. The neutral axis in all these loaded warped beams

is nearer the compression than the tension face (wet or dry) at 50% of rupture and also at rupture. The maximum extensibility in tension was from 0.015 to 0.018 per cent. The simultaneous compression was from 0.012 to 0.016 per cent.

To assume an initial stress would presuppose an elastic concrete holding this stress throughout the five days previous to the test, and an unusual distribution of stresses throughout the cross-section. Inasmuch as these initial stresses must balance, it is difficult to reconcile an initial compression in the top with a compression in the saturated bottom. This matter is left open for discussion.

Deformations Throughout Cross-Section.—In order to interpret the deformations occurring in the bottom and top of the road slab, a study was made of similar deformations observed in the warped beam units. The size of these units, 4 in. by 7 in. by 4 ft. 0 in., was chosen to give a thickness equal to that of the road slab. After initial drying, the beams were placed with the bottom in contact with wet burlap and successive observations of deformation and corresponding deflection were taken. Deformations were recorded at seven different depths between two pairs of sections in each beam. The average results for three beams are shown in Fig. 20. During nine days the lower face expanded 0.0152% and the upper face shortened 0.0024 per cent. The data locate the position of the neutral axis of deformations and show the relative deformations occurring throughout the depth of the beam. The height to which the saturation, visually observed, proceeded at the end of nine days was approximately $2\frac{2}{3}$ in., or one-third the depth of the beams.

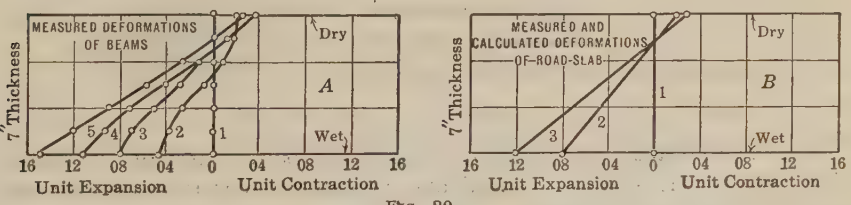

FIG. 20.

If the curve of distortion of a warped beam is assumed to be an arc of a circle, the following formula is applicable to the data:

$$d\,l = \frac{8\,h\,m}{L\,.\,L} \qquad (1)$$

in which,

$d\,l$ = algebraic summation of deformations in top and bottom of the beam;

h = depth of beam;

m = deflection;

L = length over which deflection occurs.

In checking any of the measured deflections against the deformations, or *vice versa*, by substitution in Equation (1), it is found that the calculated values (see Table 9) agree closely with the measured values (Fig. 20).

Application of Formula to Data of Road Slab.—Table 9 shows the values of the deformations computed by formula as occurring in the bottom of the road slab and resulting from flooding the sub-grade, thus saturating the bottom concrete. Here the expansions of the under side of the slab are calculated by substitution of the known measurement of the deflection and deformation of the upper surface in Equation (1). Each step in the calculations is shown.

TABLE 9.

3	" " " " (exterior ")	0.0042

Substituting in Equation (1), $d\,l$ = { 0.00010 at Point 2 / 0.00015 at Point 3

Measured unit contraction, top = { —0.000019 at Point 2 / —0.000028 at Point 3

Expansion bottom = algebraic sum, $d\,l$, top + bottom = { +0.00008 at Point 2 / +0.00012 at Point 3

Fig. 20 indicates clearly the swelling of the bottom and the shortening of the top of the slab. A neutral axis of deformations separates the two, similar to that in the subsidiary beams. The greater swelling of the concrete at the unrestrained edge of the slab and the less swelling at the interior restrained portions are shown.

The translation of the measured deformations into stresses, and the variation of such stresses throughout the cross-section, is a field of discussion of considerable interest. The corners of the slab are held up against the dead weight of the overhanging cantilever, which has been raised by the swelling of the bottom concrete. What is the state of stress in the top, which has been shortened?

APPENDIX II

REVIEW OF LITERATURE ON EXPANSION AND CONTRACTION OF CEMENTS, MORTARS, AND CONCRETE*

I.—Volume Changes

The earlier measurements of volume changes in concrete cover a wide range as to size and age of specimen, quality of cement, kind of aggregate, richness of mix, duration of exposure, time of initial measurement, etc., and, consequently, a wide range of values. More recently the importance of volume changes occurring during the first ten hours have begun to be appreciated, the underlying influences have begun to be evaluated, the nature of the action understood, and, therefore, a possibility of remedy suggested. The necessity of protecting concrete from volume changes as soon as possible after pouring is evident.

Volume changes are due to: Shrinkage and expansion; temperature changes; and plastic flow under load.

The factors influencing the shrinkage and expansion, in part at least, are:

(1) Composition of cement.
(2) Aggregate (fineness and quality).
(3) Wetness of mix and proportioning.
(4) Size of specimen, and forms (whether absorptive or not).
(5) Exposure (humidity, temperature).
(6) Age of specimen and duration of test.
(7) The time of starting measurement (before or after initial or final set).

(*1*) *Quality of Cement.*—Various brands differ markedly in their volume constancy, depending on chemical composition and fineness.

Tests by the U. S. Bureau of Standards† were made on neat cement and on 1 : 3 mortar cured in water. At thirteen weeks the expansion was: Neat cement, 0.066% (0.057 to 0.120); 1 : 3 mortar, 0.024% (0.005 to 0.012). Using the same cements re-ground, the expansion increased to 0.085% and 0.13, respectively.

Mr. John Grant‡ showed that expansion was increased when cements contained gypsum.

Recent tests at Purdue University show the changes in six brands of cement and in concrete made from certain of the brands. (See Table 4 and Figs. 3 and 4.)

D. A. Abrams, M. Am. Soc. C. E., in 1919,§ in connection with an investigation of the effect of fineness of cement, found no appreciable differences in

* No attempt has been made to discuss the early experiments, such as the thorough investigation of Professor White of the University of Michigan.

† *Proceedings*, Am. Soc. for Testing Materials, Vol. 15, 1915, p. 141.

‡ *Minutes of Proceedings*, Inst. C. E., Vol. LXII (1879–80), Pt. IV., p. 108.

§ *Bulletin No. 4*, Structural Materials Laboratory, Lewis Inst., Chicago, Ill.

volume change due to fineness, but he states that the measurements were not precise.

A paper in *Le Ciment* (1923) quotes expansion tests with Le Chatelier apparatus as shown in Table 10.

TABLE 10.

	Residue.		Expansion: Le Chatelier apparatus.
	Sieve 900.	Sieve 4 900.	
Cement A.	3%	28%	6 mm.
	2%	20%	3 "
	1%	16%	1 "
Cement B.	2 %	25%	2 mm.
	1.5%	20%	2 "
	0.5%	14%	½ "

The author remarks that this expansion may be reduced by finer grinding, providing the cement is well burned. Methods such as airing of cement will also lessen expansion. Disaggregation of concrete is attributed to the influence of gypsum, which constituent, expressed as SO_3, varies from 1.75 to 3.00 per cent. Some countries allow only one-half as much SO_3 when the cement is to be used in sea water. Experiments in Germany on concrete exposed to sea water for 10 years are quoted to show that 2.5% of SO_3 is not detrimental either in fresh or salt water. The author believes that the Le Chatelier apparatus for which 6 mm. is specified will detect expansive cements, but will reject cements that are worthy; he recommends a specification of 10 mm. (See, also, tests by Otto Graf, discussed subsequently.)

Dr. H. Nitzsche* measured the volume change of several cements with the Bauschinger apparatus. Mortars approximately 1 : 4 and of consistencies appropriate in reinforced concrete were used. The Bauschinger prisms were conditioned as follows: 2 days in moulds, 7 days in water, 10 days in room temperature, and then dried to constant weight at 50° cent. The length of the "wassergesättigt" prisms in percentage of the dry mortars was as shown in Table 11 when the cements are listed in order of increasing fineness.

Apparatus for Measuring Volume Change.—The British Standard Specifications for cement recommends the Le Chatelier method. The paste is 1.18 in.

* *Zement*, December, 1921.

in diameter and 1.18 in. high, moulded inside a split metal tube. Arms attached to each side of the split multiply the movement of the tube due to volume changes of the cement paste.

The paste is submerged in water at 58 to 64° Fahr. for 24 hours, and the position of the arms indicated. The test piece is again submerged, the water brought to a boiling temperature in 25 to 30 min., and kept boiling for 6 hours. The mould is then removed from the water and allowed to cool. The indicator arms are then read, the difference between the two measurements representing the expansion.

The Bauschinger apparatus is an arrangement for measuring the change of length of a short bar, 100 mm. in length and 5 sq. cm. in cross-section.

M. Deval* has discussed the method of measuring variations in the volume of hydraulic cements. He refers to the tests of Durand-Klaye, Debray, Bauschinger, Kleve, and Le Chatelier, and concludes that the Le Chatelier method gives the most concordant results under which cement of good quality will not show more than 0.2% of swelling. He remarks that cements differ greatly in expansion and in rapidity of hydration.

(*2*) *Aggregate.*—Mr. Cloyd Chapman† reported the contraction of 1 : 2 mortar specimens at 16 weeks to be 0.197% using screenings as aggregate and 0.083 with sand. Concrete (1 : 2 : 4 mix) with screenings contracted 0.062%, and with sand 0.042 per cent. The specimens were 2 by 2 by 24 in. in size; the measurements began 24 hours after moulding.

No doubt the aggregate has an important influence. In many cases the cause of disintegration of exposed structures is to be charged to defective aggregates, especially those containing a large proportion of fine limestone dust or clayey material. Porous concrete with changing moisture content must be subject to strains due to alternate expansion and contraction.

(*3*) *Proportioning.*—Leanness of mix diminishes the volume change. A number of investigations evidence this. Thus, a comparison of neat cement with 1 : 3 mortar gives the results shown (percentage) in Table 12. Evidently, as the mix becomes leaner the volume changes diminish.

Pearson's tests show the relative shrinkage of various mortars, the initial measurements being made while the specimens were plastic, as follows:

Mix.		Percentage of shrinkage.
Neat		0.217
1 : 1		0.123
1 : 2		0.110
1 : 3		0.109
1 : 4		0.094
1 : 5		0.086
1 : 6		0.084
Concrete	1 : 4	0.067
	1 : 6	0.050

In the tests of Goldbeck on 8 in. by 8 in. by 5-ft. beams* a wet or dry mix of 1 : 2 : 4 or 1 : 3 : 6 concrete varied but little in contraction when exposed to air for 1 year, the extreme ranges in percentage as scaled from a diagram being as shown in Table 13.

TABLE 13.

	30 days.	60 days.	1 year.
1 : 3 : 6 mixed very wet (10 to 12% water)	0.023	0.033	0.053
1 : 3 : 6 mixed very dry (8.5% water)	0.034	0.045	0.055
1 : 2 : 4 mixed very wet	0.023	0.034	0.058
1 : 2 : 4 mixed very dry	0.035	0.040	0.055

Tests at Purdue University on gravel concrete when measurements began 2 days after moulding showed for 1 : 2 : 3.5 and 1 : 1.5 : 3 concrete an expansion in water during 40 days of 0.005 per cent. During 150 days subsequent drying in air the contraction was 0.035 and 0.015%, respectively, the brands of cement varying in the two concretes.

Dr. Mörsch has recorded† tests of the influence of richness of mix and also of different varieties of sand and the volume changes due to swelling in water and shrinking in air. For one year the swelling in water continually increases

* *Bulletin No. 532*, U. S. Dept. of Agriculture, 1917.

† "Der Eisenbetonbau," Fifth Edition, Vol. I, pp. 32–33.

for neat cement, and for 1 : 3 and 1 : 5. mortars; the shrinkage in air reaches a maximum at 90 days. The relative values at the end of a year for swelling in water are:

Neat cement	180
1 : 5 mortar	45

For shrinking in air the values are:

Neat cement	150
1 : 5 mortar	52

The volume changes of mortar made with several sands seem to differ.

(*4*) *Size of Specimen and Forms.*—Evidently the size of the specimen, which affects the rapidity of loss and gain of moisture and the unequal distribution of moisture, will have a marked influence on shrinkage and expansion. Consequently, the data from many investigations are not comparable. Flat specimens will warp; there will be different frictional resistances due to the forms or to the bending on the supports. Moreover, the size of the specimen will control the early formation of surface cracks, which must affect the integral movements. Pearson has shown that absorptive forms will greatly reduce the shrinkage of mortar specimens. Graf has shown that shrinkage is lessened during early stages by forms with cast-iron ends. For these reasons the specimen itself and the technique of testing should be standardized for these tests which now seem to be of increasing importance. The specimens used range in nominal size from 5-in. cubes to prisms, 2 by 2 by 4 in., 2 by 2 by 24 in., 1 by 4 by 24 in., 1.5 by 1 by 4 in., 4 by 4 by 24 in., 8 by 4 by 2 in., 8 by 8 by 40 in., and 8 by 8 in. by 9 ft.

Mörsch* shows the effect on tensile strength of varying the size of the test piece from 5 sq. cm. to 400 sq. cm. (Table 14).

TABLE 14.

Cross-section, in square centimeters.	Tensile Strength, Neat.		Mortar.
	28 days moist.	7 days moist; 21 days dry.	
5	33.4	44.8	1 : 1.34
100	21.0	15.9	0.76
400	17.6	12.0	0.68

The effect of desiccation of briquettes following 1 day in air and 21 days in water is shown by a rapid decrease in strength and a gradual increase in strength following a longer period of desiccation, until at 12 days the strength of the briquettes exceeded the strength at the time they were taken from the water.

One aspect of surface drying and the production of fine surface checks is the consequent loss of strength in cement briquettes which have been allowed

* "Der Eisenbetonbau," 1920, Vol. I, p. 121.

to dry subsequent to immersion and previous to testing. In 1904, Van Ornum* determined the effect on tensile strength of taking briquettes from the storage tank for various periods before testing. The strength of the neat Portland cement decreased as much as 50% when exposed to air from 1 day to 3 days.

M. Anstett,† Chief of Laboratories of the City of Paris, France, made similar tests in 1922, and reported the decrease in strength of neat briquettes tested at 7 days, 37 days, and 90 days, after having been removed from the water 7, 20, and 26 hours, respectively. If the briquettes are allowed to dry for 7 hours before testing a loss of strength of 10% may be expected. This becomes an important matter in standardizing cement testing. In the case of 1 : 3 mortar briquettes, the loss is less marked, being approximately 5 per cent. The loss increases in proportion to the duration of the drying period.

No doubt the effect of drying will depend on the cement used, and the method of forming the briquette, on the rate of drying.

In a book by Foker and Barnes, on "Reinforced Concrete Design", published in 1912, they quote‡ tests on 1 : 3 mortar specimens that were cured in air 1 day and in water for 27 days, and afterward exposed to dry air for various periods up to 12 days. After a period of drying for 2 days the strength diminished 50%, following which it increased to approximately its value at the end of the water-curing period.

The surface shrinkage no doubt will affect the point in the extensibility of the tension side of beams at which hair cracks are observed. Beams carefully cured or saturated will probably show greater extensibility. A close analogy exists between concrete and wood that is case-hardened by defective kiln practice.

In the absence of reinforcement near the surface, it would appear that surface shrinkage might increase the number of hair cracks.

(*5*) *Exposure.*—Many early tests disclosed swelling in water and shrinkage in air. The wide ranges of values recorded were mystifying as the underlying controlling factors were not known. Exposures include immersion in water (cold or hot), a covering of wet burlap or damp sand, dry or moist air, all with various temperatures. The effects of humidity and temperature, while minor as compared to other factors, are not negligible.

The results of various measurements, therefore, are indicative of ranges rather than of definite application in specified cases.

Professor H. H. Scofield§ measured the change of length of mortars and concretes with and without an admixture of hydrated lime. The specimens were 4 by 4 by 24 in. He reports that the degree of volume change depends on the conjunction or opposition of temperature and moisture influences. A change of temperature in 1 : 5 mortar with fine sand screened out, age 8 weeks, from 33.8° to 180° Fahr., increased the length + 0.075%, or 0.00000535 per degree. In a change from 180° to 18° Fahr., the shrinkage was — 0.0664 per cent. From 22° in air to 107° Fahr. in water, the change was + 0.0377%; and from 107° Fahr. saturated to 18° Fahr. outside air, — 0.0467 per cent.

* *Engineering News*, Vol. 51, p. 24.

† *Revue de Matériels de Construction et Travaux Publiques*, 1922, Vol. 148, p. 1.

‡ *Mitteilungen über Forsch.* und *deut. Ing.*, Heft 72–74.

§ *Proceedings*, Am. Concrete Inst., Vol. 13, 1917.

The changes of length due to absorption of water were found to be as follows: From 71.5° Fahr. in air, to 71.5° Fahr. in water (24 hours) + 0.0192%; from 71.5° Fahr. in air to 100° Fahr. in water (72 hours), + 0.040%; from 100° Fahr. saturated to 10.4° Fahr. in air, — 0.0553 per cent.

For 1 : 5 gravel concrete giving a tensile strength of 2 314 lb. at the age of 7 weeks, these values become + 0.017%; + 0.036%; and — 0.0472 per cent.

In these tests a comparison is made between the shrinkage of wet and dry specimens under a sudden drop in temperature. The wet specimens shrank — 0.0553%, and the dry ones, — 0.0664 per cent. However, the sand used was different in the two cases.

Scofield's tests also show that admixtures of hydrated lime increase the volume and strength.

H. C. Berry,* M. Am. Soc. C. E., found that 1 : 2 : 4 concrete shrunk in air at 150 days, 0.023% and expanded in water, 0.020 per cent. This is less difference between shrinkage and expansion than in other experiments.

Mörsch† averages the results of tests on mortars, 1 cement and 3 sand, immersed in water for 7, 28, 90, and 196 days, and then allowed to dry in the air for periods ranging up to 4 years.‡ A set of test pieces was allowed to dry without immersion. His diagram is reproduced in English units in Fig. 21.

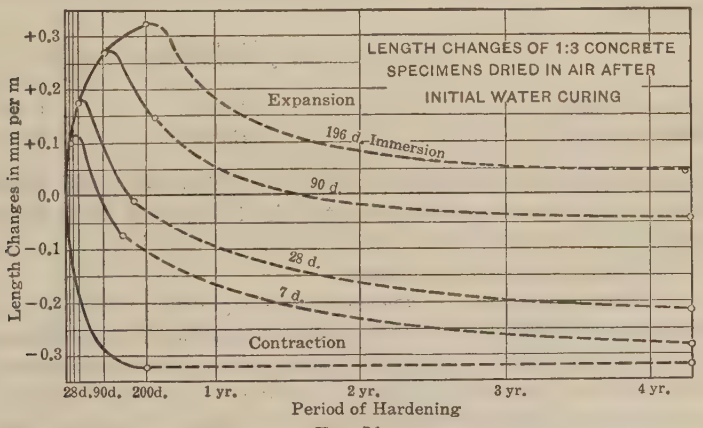

FIG. 21.

Professor F. R. McMillan,§ reviews tests of shrinkage specimens, 4 by 5 by 24 in., cured 2 weeks under wet burlap and afterward exposed to the ordinary air of the laboratory. The shrinkage was from — 0.055 to — 0.065 per cent. Initial readings were taken when the beams were 1 day or 2 days old. The shrinkage amounts to — 0.05% within the first 6 days. The effects of varying the proportions, quantity of water, or density were small. He states that the minimum shrinkage to be expected in concrete that has been allowed to dry out thoroughly is — 0.05 per cent. Values from 20 to 50% greater will usually result; the difference in early curing conditions has little effect on the final shrinkage.

§ *Transactions*, Am. Soc. C. E., Vol. LXXX (1916), p. 1378.

De Breuville* subjected reinforced plates to water pressure, off and on, to obtain the effect of moving water on the bond between mortar and steel. He concludes that moving water weakens the bond.

G. E. P. Smith, M. Am. Soc. C. E., explains† longitudinal cracks along the top of 20-in. concrete pipe at Tucson, Ariz., by the action of water swelling the bottom of the pipe. Experiments on dry pipe, partly submerged, appear to confirm this explanation. Tests of pipe, 28 days old, showed a strength of 2 624 lb. per lin. ft. for dry pipe and 1 790 lb. per lin. ft. for pipe that had been immersed for 5 hours.

Lagaard‡ tested 1:2:4 limestone concrete in compression. The specimens were cured for 7 days under wet sacks and approximately 450 days in air. One set showed a value of E of 3 700 000 and a compressive strength of 3 630. The other set subsequently immersed in water for 21 days showed a value of E of 3 150 000 and a compressive strength of 2 340, all in pounds per square inch.

Tests§ by G. M. Williams, Assoc. M. Am. Soc. C. E., showed no difference in the value of E, either for immersed or dry concrete, or for a low or high degree of consistency. In the discussion of this paper, Professor Walker, of the Lewis Institute, takes issue on this conclusion. His values, in pounds per square inch, are:

	Wet concrete. One year in wet sand.	Dry concrete. One year in wet sand. One month in air.
Compressive strength	4 950	5 920
Initial value of E	7 450 000	9 300 000

(6) *Age of Specimen and Duration of Test.*—Expansion and contraction continue for extended periods. The variation in duration of the tests accounts for differences in reported results. Rich specimens that have been saturated for extended periods become impervious.

(7) *The Time of Starting Measurements.*—In general, the initial observations of volume changes in the investigations reviewed, were taken subsequent to the setting periods. Pearson's investigations on plastic mortar show the marked volume changes that occur during the setting period. It is obvious from this standpoint, therefore, that the data of the many investigations are not to be compared.

In 1921,‖ Pearson investigated the development of change of length of mortars as time elapsed, especially during the first few hours. Up to 6 hours, while mortars were plastic, the shrinkage was moderate, but at the time of initial set, the volume changes were pronounced. They moderated after 10 hours. At the time of final set the material quiets down, and various cements then show about the same rate of shrinkage. When specimens were placed on non-absorptive bases the shrinkage at 64 days was: Neat cement, 0.21%; 1 : 3 mortar, 0.19%; 1 : 6 mortar, 0.084 per cent.

* *Annales des Ponts et Chaussées*, Sem. III, 1902.
† *Engineering News-Record*, 1919, v. 831.
‡ *Loc. cit.*, November 14, 1918.
§ *Proceedings*, Am. Soc. for Testing Materials, 1920, p. 8233.
‖ *Proceedings*, Am. Concrete Inst., 1921, p. 135.

For the first two or three hours while mortars are still plastic, either moderate expansion or contraction may occur due to manipulation, forms, and the quality of the cement. At the time of initial set there is a tendency toward pronounced contraction which moderates at 8 to 10 hours when final set is approaching. From 12 to 24 hours is a period of comparative quiet, with slight shrinkage. There is then a long continued shrinkage which persists for many months; at one year this may range from 0.15 to 0.34 per cent. The volume change, therefore, is in two phases as follows: (1) Plastic, 12 hours to, say, 24 hours; (2) rigid after 24 hours, changes here are independent of those in Phase (1).

Dr. Otto Graf,* of the Testing Laboratory of the Technical High School of Stuttgart, has made valuable investigations of the volume changes of mortars. The 1921 paper reports the progressive shrinkage of mortars from 1 hour to 28 days, and the effect of excess water. Four brands of Portland cement were used. The mortar was 1 : 1 by weight, and the water varied from 10% (firm consistency), 15% (soft consistency), and 19% (plastic consistency). The test piece was a disk, 15 mm. thick and 150 mm. in diameter, placed on oiled paper and moved under a microscope by a micrometer screw. His results are reproduced in Figs. 22 and 23. The importance of dry concrete and early curing to reduce shrinkage is evident. Damage due to shrinkage originates during the first ten hours.

Fig. 23 substantiates Abrams' results, showing the effect of water on strength, and emphasizes the value of dry concrete.

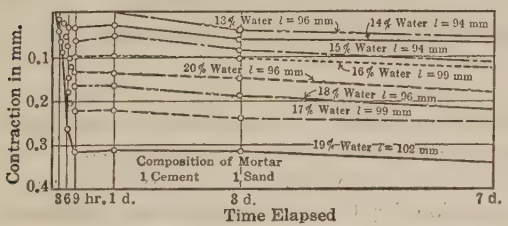

FIG. 22.—SHRINKAGE OF 1 : 1 MORTAR.

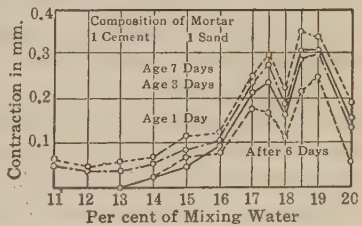

FIG. 23.—EFFECT OF WATER ON SHRINKAGE.

Graf also reports the marked effect of the cement content on the volume change. The shrinkage in a length of 100 mm. was as shown in Table 15.

TABLE 15.

Time.	9 hours.	7 days.	1 day to 28 days.
Neat cement	0.42 mm.	0.52 mm.	0.13 mm.
1 : 1 mortar	0.32 "	0.38	0.08 "
1 : 4 mortar	0.05 "	0.13	0.07 "

The four brands of cement used varied greatly as to the volume changes during the first 9 hours.

* *Beton und Eisen*, 1921–22.

In tests of prisms, 80 mm. square and 400 mm. long, made to detect the differential movements between the concrete and the embedded reinforcing bars, it was found that within the first day while considerable changes in volume took place in the mortar, no changes of length were recorded in the reinforcement. This condition lasted for three days.

In the 1921 tests of Graf, wax and oil were used to prevent the mortar from adhering to the sides of the moulds. In 1922, moulds of cast iron were used to study the effect of adherence of the concrete to these surfaces. Reinforced specimens were also studied. The concrete was 1 : 1.2 : 1.8, using 11.8% water.

It was shown that the contact with the ends of the cast-iron moulds lessened the natural shrinkage of the concrete. Reinforcement considerably reduced the shrinkage of concrete during the first day after moulding; plain concrete specimens show a reduction, in a length of 333 mm., of 0.004 cm. and reinforced concrete, of 0.0008 cm., after 9 hours. After 14 days, these values become 0.0024 and 0.0004 cm., respectively.

Volume Changes Due to Temperature.—The generally accepted value of the coefficient of expansion for concrete due to temperature is 0.0000065 for 1° Fahr. It is assumed to be constant throughout the ordinary ranges of temperature.

Professor Mills, of Cornell University, reports* a series of tests for the coefficient of temperature expansion using test pieces 8 by 4 by 2 in. The coefficient ranges from 0.00000783 for neat cement to 0.00000577 for 1 : 5 mortars; for concrete, 0.00000677 for 1 : 1.5 : 3 mix to 0.00000537 for 1 : 3 : 6 mix. In age the specimens ranged from 1 month to 8 months, and in temperature from 70° to 212° Fahr.

In 1901, at Purdue University,† W. D. Pence, M. Am. Soc. C. E., measured the expansion of 1 : 2 : 4 concrete specimen, 4 in. in diameter and 3 ft. long, placed inside a steel cylinder into which steam was introduced. The temperature range was 65° Fahr. Both stone and gravel aggregates were represented. The coefficient of expansion for 1° Fahr. ranged from 0.0000052 to 0.0000057 in stone concrete; a stone bar showed 0.0000056; gravel concrete averaged 0.0000056. These tests well represent average values. However, it was assumed that the coefficient is equal throughout the range of temperature, and no doubt there was also expansion due to the steam, if it was moist.

Fig. 6 shows the results of tests at Purdue University. The observations were conducted on completely dried specimens only, so that there is no error due to the change in length with fluctuations in the moisture content of the concrete.

Plastic Flow.—The yielding of concrete under continued loads was noticed at an early date, especially in laboratory tests to determine the modulus of elasticity. This plastic flow became of practical importance in specifying and measuring deflections of loaded floor panels. Later, it became apparent that it produced a readjustment of stresses between steel and concrete which was important from the standpoint of the design of floors and columns.

DISCUSSION

A. T. GOLDBECK,* ASSOC. M. AM. SOC. C. E. (by letter).—Those having to do with design are likely to consider the safety of concrete structure from the standpoint of its ability to carry loads. The life of many structures has been limited by factors other than ability to carry the loads for which they were designed. It is recognized that concrete highways are subjected to stresses of considerable intensity, which are produced by agencies other than the wheel loads of traffic, and a thoroughly rational procedure in the design of concrete pavements must give due weight to all the high stress-producing possibilities. It is known, of course, that temperature change brings about high stress in concrete pavements, and it is also quite apparent that moisture is another very active stress-producing agent.

The present investigation was made to obtain more exact information on the influence of moisture on concrete highway design. The author is to be commended on the careful and painstaking manner in which the present series of tests were conducted. The careful design of apparatus and attention to necessary detail in the conduct of the work are reflected in the character of the results obtained. The author has corroborated the general results obtained by other investigators in this field, namely, that Portland cement mortar or concrete shrinks on drying and expands when kept moist. It is significant, however, that the percentage of contraction on drying differs greatly in different brands of cement. Obviously, this must be an important element in the relative number of shrinkage cracks in concrete roads after the initial period of curing. It is desirable, of course, that the cement should shrink as little as possible. The variable coefficient of expansion with temperature shown by these tests is a fact that has not generally been recognized, for it is quite the custom to use a constant value for the coefficient of expansion irrespective of the temperature. Apparently, the value for the coefficient of expansion at ordinary air temperatures is about 0.00000425, which is somewhat lower than the value ordinarily accepted.

The values obtained by Professor Hatt might be well worth while corroborating through another series of investigations. Values obtained for a change in length of 1 : 2 : 3.5 concrete in general check with those obtained by the writer.† The decrease of contraction depends apparently not only on the character of the cement, but it has been the writer's experience that much also depends on the dryness of the atmosphere, for it has seemed that even a short period of high humidity could be detected through the slight expansion of a very dry specimen.

It is to be noted that the percentage of expansion of concrete kept moist is considerably lower than the percentage of contraction of concrete permitted to dry out. This conclusion likewise was borne out in the writer's experiments along this line. The effect of a period of wet weather on specimens exposed to the atmosphere is likewise clearly demonstrated. It is to be noted, however,

* Director, Bureau of Eng., National Crushed Stone Assoc., Washington, D. C.

† *Bulletin No. 532*, U. S. Dept. of Agriculture.

that the rate of change of length of the specimen is quite slow, not only in expansion, but also in contraction. It has often been noticed that the greatest percentage of "blow-ups" in concrete pavements occurs in the spring and that as the summer progresses the pavement settles back into position. This phenomenon is readily explained by the tests just reported by Professor Hatt, for in the spring the sub-grade is in its wettest condition. The concrete, therefore, is expanded not only by moisture, but by the high temperatures during that period. Gradually, the moisture evaporates and during the summer the concrete shrinks somewhat and is subjected then only to the expanding action of high temperature.

The lesson to be learned from Fig. 10 evidently is that engineers need not be afraid of the structural strength of concrete as long as it is in a frozen condition, but that its weakest condition is immediately after thawing or when it is saturated. The measurements on the movement of the corner of the road slab, depending on the extent of saturation from bottom to top, are what might be expected, and the deformations calculated from these deflections agree strikingly well with the measured deformations.

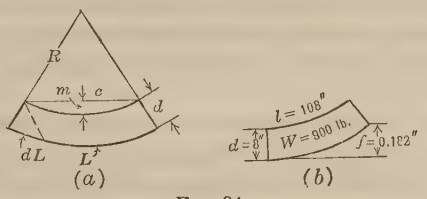

FIG. 24.

Perhaps it is not generally realized that under unfavorable conditions a rather high stress might be created transversely in a concrete slab due to a condition of high moisture at the bottom of the slab as compared with a dry condition at the top. For an 18-ft. slab, the following calculation shows that theoretically a stress produced by deflecting the end of an 18 ft. by 1 ft. by 8-in. concrete beam to its original shape after it had been warped because of difference of moisture content between top and bottom, may approximate the modulus of rupture of concrete.

From Fig. 24 (*a*):

$$R = \frac{c^2}{8\,m}; \quad R = \frac{d \times L}{d\,L}; \quad c = L; \quad d\,L = c'\,L$$

c_1 = unit change in length between top and bottom fibers = 0.00025.

By substitution:

$$m = \frac{c' \times L^2}{8d} = \frac{0.00025 \times 216 \times 216}{8 \times 8} = 0.182 \text{ in.}$$

Assuming the beam to be supported at the center, each half becomes a cantilever of length = 108 in. (Fig. 24 (*b*)).

The deflection due to weight of beam is:

$$f = \frac{W\,l^3}{8\,E\,I} = \frac{900 \times 108 \times 108 \times 108 \times 12}{8 \times 3\,000\,000 \times 8 \times 8 \times 8 \times 12} = 0.094 \text{ in.}$$

The stress produced by weight of beam is:

$$\frac{W\,l}{2} = \frac{S\,I}{C}\;;\quad S = \frac{W\,l\,c}{2\,I}\;;\quad S = 380 \text{ lb. per sq. in.}$$

The remaining deflection of 0.088 in. will be accompanied by a stress of 271 lb. per sq. in., and was found from the formula:

$$S = \frac{3\,f\,E\,d}{2\,l^2}$$

The total stress will be:

$$380 + 271 = 0.651 \text{ lb. per sq. in.}$$

This calculation assumes that the slab is bent back into a plane by passing vehicles after it has been warped by the unequal distribution of moisture from the bottom to the top of the slab. This condition is, of course, an extreme one and is generally not obtained. Nevertheless, the possibility of very high stress is quite apparent. It should be borne in mind that, in general, the extremes of moisture which can be obtained under laboratory conditions are not likely to occur in the field, for usually the evaporation and saturation are not carried to completion in the field, due to the intervening influence of periods of dry and hot weather and to the influence of capillary moisture from the sub-grade.

The study of the effect of moisture on concrete would not be complete without further study of the effect of repeated loading on wet concrete as well as on dry concrete. Professor Hatt and others have shown that repeated loads have telling effect when they produce a stress much in excess of the modulus of rupture of the concrete, the concrete being dry. It would be interesting to learn whether the effect of repeated loads might not be more severe on concrete in a saturated condition.

G. E. P. Smith,* M. Am. Soc. C. E. (by letter).—It has been realized for a long time that climatic effects on concrete are of great importance, and that quantitative data adequate for designing and for determining practice in light construction exposed to the weather, such as sidewalks, are lacking. This paper is, therefore, exceedingly welcome at the present time. Much still remains to be done, and it is to be hoped that in laboratories properly equipped for this work, investigations will be continued until the causes of change of volume and the factors which govern variation in the effects of temperature and moisture are well understood. In Southern Arizona and regions of similar climate, where the relative humidity may be less than 20% for many days in succession and where hot, dry forenoons are followed by rainy afternoons, the importance of such knowledge is evidenced by the prevalence of crazing marks and by the large percentage of concrete construction which is disfigured by cracks or which becomes disintegrated until replacement is necessary. Engineers speak of "concrete for permanence", and would be happy to feel assured that the motto is reliably true with respect to even severe weathering conditions.

* Prof. of Irrig. Eng., Univ. of Arizona, Tucson, Ariz.

In 1918, the writer called attention* to some important failures of concrete pipe lines at Continental, Ariz., and to similar failures in California. At Continental, cement pipe made on a McCracken revolving packer-head machine—pipe of unquestionably high-grade quality—failed soon after being put in service, by longitudinal cracks, in one case by a crack approximately 1 000 ft. long. The pipe had been allowed to stand in the stockyard until it had become thoroughly dry. The differential expansion in the shell due to absorption of water must have produced high tensile stresses, inasmuch as the pipe when tested withstood the stress produced by a pressure head of more than 100 ft. of water. The pipe was too "good", it broke itself; weak, porous, hand-tamped pipe never fails from this cause. In a study of the causes of these failures it was found that a joint of pipe immersed in water gained 5% in weight with an elongation of 0.056 per cent. A joint that had been broken in the internal-pressure testing machine and, therefore, had an open crack on one side, was tested by immersing one-half the pipe, laid flat, in water. With the absorption of water, mostly from the outside, the crack closed rapidly about 0.045 in. and then slowly opened again.

When the pipe-laying program at Continental was terminated, there was a considerable supply of 12-in. and 14-in. and some 16-in. pipes on hand, stacked three tiers high in the stockyard. These pipe have laid undisturbed for seven years exposed to sun and rain. When he examined them recently, the writer discovered that fully one-half the pipes were in bad condition and that about 10% of the top layer had cracked wide open. Fig. 25 shows the condition of the exterior and Fig. 26 of the interior of one of the pipes. Most of the cracks start at the tongue end.. The hubs or grooves break off circumferentially. None of the pipe of this size failed underground, although similar 20-in. pipe failed by longitudinal cracks along the top of the pipe line.

The crazing on the exterior shows that the shrinkage has been both circumferential and lengthwise. On the interior, the circular cracks are more pronounced, and occur somewhat regularly beneath the corrugations or beads of the outer surface, due probably to the fact that the force of expansion is greater in the section beneath the beads than elsewhere.

Apparently the expansion of the outer part of the pipe wall produced the interior cracks and the rapid shrinkage of the outer part caused the crazing of the exterior surface. McCracken pipe has a very dense interior surface. Hence, most of the absorption of water and drying out is through the outer surface. The cracks tend to occur at those parts of the pipe that are relatively the most dense.

Whether temperature or moisture was the more active agent is uncertain. Professor Hatt has shown† that the coefficient of expansion is relatively high at high temperatures, such as occur at Continental during the summer, but with the free circulation of air through the open-ended pipe in the stack, it would seem unlikely that the difference in temperature between the outer and inner surfaces would be great.

† See p. 278.

Crazing cracks are common, also, on building floors that are continuously dry, and these cracks become progressively more pronounced year by year. Sidewalks, ornamental park benches, and building steps in Tucson, Ariz., suffer greatly from crazing cracks which develop into breaks and disintegration. Fully one-half the concrete sidewalks have a too limited life. Some of these results can be traced to poor workmanship or faulty curing, but by no means all of them.

The U. S. Bureau of Standards has investigated the properties of cement having a high magnesia content.* The effect of varying percentages of magnesia on the expansion when immersed and the contraction when dried indoors was studied by means of 5 by 5 by 45-in. bars. An inspection of the published results indicates that, neglecting two cements that were under-burned and unsound and three others, of the high alumina series, that were manifestly abnormal, the expansion from moist-chamber to air-dry condition varies directly with the percentage of magnesia. The cement used in the pipe at Continental had a high magnesia content, and there is a strong presumption that this had much to do with the failures of the pipe lines and the destruction of the pipe in the stockyard.

The shape of the pipe is such as to bring out to its fullest extent the injurious action of differential expansion. For massive construction and in humid climates, the effects may be inconsequential, but it is probable that for severe conditions the specifications of cement should contain a clause limiting the contraction of 1 : 3 mortar to, say, 0.02% in 1 month, or 0.03% in 3 months, and the methods of conducting tests should be standardized.

It is of great interest to note that Professor Hatt found wide differences in the effect of moisture on expansion and contraction in the six different brands of cement tested. The variation in the coefficient of expansion due to temperature was slight. It would be of value to know the percentages of magnesia in the six brands.

The thermal coefficient stated in the author's conclusions seems to be based on the oven-dry specimen reported in Fig. 6. The air-dry specimens have much higher coefficients.

In the case of the beams warped by the saturation of the under side, can it not be assumed that a part of the resulting compression on the bottom is relieved by warping, causing compression in the top side, and that tension exists in the beam between the line of saturation and the neutral axis to such an extent that the horizontal initial forces (stresses) are balanced? It may be remarked that, if the conditions shown in Fig. 20(*A*) are reversed, starting with a saturated beam, the effects on the beam will be much more injurious.

During saturation of specimens of cement pipe at Tucson, it was found that the expansion lags somewhat behind the absorption, suggesting that a change in crystallization is taking place, with the addition of water to the molecule.

W. K. Hatt,* M. Am. Soc. C. E. (by letter).—Experiences related by Professor Smith show the effects of expansion of the lower part of a concrete pipe under extreme conditions. It will be necessary to know something more about the manufacture of pipe in order to judge whether or not these examples are representative. In a paper published by the U. S. Bureau of Public Roads, entitled "Concrete Pipe for Use in Irrigation",† warning is given against laying such pipe in sandy soil that is hot and dry. It would appear that extra precaution should be taken in the curing of pipe in climates such as that of Arizona, because it is well known that surface crazes result from improper curing with extreme exposure. These conditions indicate the desirability of using mesh reinforcement.

During May, 1925, tests were made at Purdue University on two 30-in. concrete pipes, machine made, of 1 to 5 mix. The pipes were 3½ in. thick and one was reinforced with mesh. They had been steam-cured and air-dried for approximately 3 months. After submerging them in water to one-third of their depth for 5 days, measurements were made around the inner and outer surfaces with a Berry strain gauge. No cracks were apparent to the unaided eye. After this test the pipes were loaded in the testing machine and crushed; each pipe tested 2 500 lb. per lin. ft.

There is usually a difference in the behavior of new and old concrete under test. In old concrete small fissures appear but the pipe continues to take more load, whereas in newer concrete the pipe seems tougher and the first visible crack corresponds more nearly to the maximum load.‡

The behavior of concrete under moisture, temperature, and load has been discussed at greater length in a paper entitled "Researches in Concrete."‡

Paper No. 1578

THE ATMOSPHERE AND ITS RELATIONS TO HUMAN HEALTH AND COMFORT*

By C.-E. A. Winslow,† Esq.

With Discussion by George A. Soper, M. Am. Soc. C. E.

When the wise king of the Hebrews sought to express the fundamental unity of the problems which confront each human life he began with the atmosphere. "When I was born", he says, "I drew in the common air, and fell upon the earth, which is of like nature, and the first voice which I uttered was crying, as all others do." "The common air" is indeed the basic condition of human existence, controlling it in more ways than are yet fully realized. The atmosphere in its relations to human health and comfort seems, therefore, a topic peculiarly appropriate for consideration by a group of men whose objective is the application of the principles of engineering science in the special field of sanitation.

The chief business of science, as the speaker understands it, is to unify and simplify conceptions of the chaos of phenomena by relating those phenomena to underlying laws and principles. This task is more difficult in biology than in mechanics or hydraulics because the reactions of living matter are more complex than those of non-living substances. The basic conditions of life are, however, suspectible of relatively simple statement. From the amœba to man, from the bacterium to the oak tree, the life process depends upon at least five essential factors, each present to an extent above a certain minimum and in general below a certain maximum. The five positive essentials are:

1.—Food (including under this term regulative mineral salts).
2.—Oxygen.

* Address presented before the Sanitary Engineering Division, New York, N. Y., January 20, 1925.

† Prof. of Public Health, Yale School of Medicine, New Haven, Conn.

3.—Water.
4.—Temperature.
5.—Light.

In addition to these positive essentials, there must be freedom from:

1.—Mechanical injury.
2.—Toxic chemical substances.
3.—The attacks of hostile living beings, predatory or parasitic.

The list is obviously not a logically complete and perfect one. One factor, that of atmospheric pressure, which is omitted from the list will be discussed. The speaker is inclined, however, to believe that it includes all but a minor fraction of those influences which under actual conditions affect the vital processes of animals and plants. Taking it for what it may be worth, it will be noted that so far as man is concerned in all but one of the life factors noted, the atmosphere plays a more or less important rôle. We do not derive food directly from the air about us, although our supply of plant food depends largely upon atmospheric nitrogen, and the prevalence of goiter in certain regions is correlated with the presence or absence of iodine salts blown inland from the sea. Oxygen, temperature, and light as they affect the human body, and to a less extent the aqueous exchanges of the body, are directly related to atmospheric conditions; whereas the air may bear with it physically injurious dust particles, toxic gases, and, under certain conditions, the microbes of disease.

Composition and Characteristics of the Atmosphere

Before proceeding to discuss the more significant deviations from normal atmospheric conditions, as they affect health and comfort, it will be desirable to recall for a moment what these normal conditions are, to which the human body is presumably more or less perfectly adapted.

The atmosphere of the earth is a layer of gases, of continuously decreasing density as one passes outward from the surface of the earth itself, and of varying composition when one reaches a distance where the decrease of gravitational force is so great as to show a marked differential effect upon its various constituents. Thus, at a height of 20 km., it is estimated by Wegener that argon has practically disappeared and oxygen is reduced to 15%, whereas nitrogen has increased to 88 per cent. At 100 km., oxygen and nitrogen have practically disappeared, the atmosphere consisting of 67% hydrogen, 4% helium, and 29% of a hypothetical gas lighter than hydrogen, which Wegener called geocoronium. Whether or not these assumptions are sound is, however, of little practical moment to the sanitarian. The atmosphere as a whole has been estimated to be made up of nearly 4 000 000 000 tons of nitrogen (73% by weight), more than 1 000 000 000 tons of oxygen (23% by weight), nearly 160 000 tons of argon and other inert gases (3% by weight), and more than 50 000 tons of water vapor (1% by weight). As water vapor is so highly variable a constituent it is usually omitted from statements of the normal composition of the atmosphere; and this normal composition at or near the surface of the earth may be stated in the usual form as nitrogen, 78.1% by volume, oxygen,

20.9% by volume, and argon, 0.9% by volume. Carbon dioxide is normally present to the amount of 0.03% and the inert gases other than argon (neon, helium, krypton, xenon) in still smaller proportions.

The constancy of the relation maintained between the four principal gaseous constituents of the atmosphere is a striking phenomenon. Nitrogen and argon, being relatively inert, might be expected to show but slight variation. Oxygen on the other hand is constantly being removed by the respiratory action of plants and animals and by processes of combustion and is constantly being contributed by the process of photo-synthesis as carried out in the green parts of plants during the day. Carbon dioxide is being consumed in the process of photo-synthesis and in the secretion of calcareous skeletons by various animals; while it is produced by respiration, by combustion, and by volcanic action and other subterranean processes. The extent of these changes may be suggested by the calculation that 1 hectare of oat field or forest (about 2½ acres) consumes in an average summer season about 11 000 kg. of carbon dioxide and gives off about 8 000 kg. of oxygen. These changes produced by 1 hectare of agricultural land during the summer would be just about balanced by the respiratory activity of 32 human beings during the whole year.

With carbon dioxide, the waters of the ocean exert an important regulative influence, dissolving in the form of bi-carbonates any excess of the gas and yielding it up again as carbonic acid when the partial pressure in the air above decreases. As a net result of these complex processes the proportion of oxygen in winter or summer, in town or country, and even in the interiors of dwellings, rarely varies near the surface of the earth beyond the extreme limits of 20 and 21% of the atmosphere by volume; the variations in carbon dioxide as will be pointed out subsequently are somewhat wider.

Atmospheric moisture on the other hand varies widely from exceedingly small proportions to a point of approximate saturation. The saturation point itself depends directly upon the temperature of the atmosphere. Air at 0° Fahr. will hold only 0.5 grains of water vapor per cu. ft.; at 20° Fahr. the amount increases to 1.2 grains; at 32° Fahr. to 2.1 grains; at 68° Fahr. to 7.5 grains; and at 98° Fahr. to 18.7 grains. Thus, there is actually more moisture per cubic foot in air at 80° Fahr. with 20% relative humidity than in air at 35° Fahr. with 80% relative humidity; but the warmer air of lower relative humidity will be much more avid in absorbing moisture from the body or other moist surfaces and will thus be much more drying in its physiological effects. Desert air and the air of heated rooms in cold climates may fall as low as 10% of their potential saturation value.

In addition to its various gaseous constituents the atmosphere usually contains a greater or less proportion of minute suspended particles in the form of dust, the significance of which will be discussed in a subsequent paragraph; and, finally, in even the briefest review of the composition of the atmosphere, we must mention living micro-organisms, present only in very small numbers in pure outdoor air, as Pasteur demonstrated when he opened his flasks of putrescible liquid upon the Mer de Glace, but often rising to hundreds per cubic foot indoors and, when considerable contaminated dust is present, even to much higher figures.

The Physiological Effects of Atmospheric Pressure

The first problem which naturally suggests itself in connection with the relation of the atmosphere to human health and comfort is that of the influence of quantitative changes in concentration due to differences in atmospheric pressure. The pressure itself is apparently not a factor of primary importance although under certain circumstances sudden changes in pressure may produce serious and even fatal results. In the construction of tunnels and the laying of foundations the workers in caissons are exposed to pressures which may exceed three or four atmospheres. While under an excess pressure of even 50 lb. per sq. in. no marked discomfort is experienced, if the return to normal pressure is made too rapidly, caisson disease or compressed air illness frequently results. In the building of the tunnels under the East River, New York, N. Y., 3 692 attacks of compressed air illness with 20 deaths were recorded in a group of 10 000 employees. The pathology of this disease appears to be a relatively simple one, originating in the direct liberation within the blood vessels or tissues of bubbles of nitrogen gas with inevitable mechanical injury; and of course the condition can be controlled by regulated and gradual decompression.

Far more important than such direct variations in atmospheric pressure are the indirect effects due to changes in oxygen concentration. Oxygen is after all the most essential contribution of the atmosphere to human health and comfort; and the predecessors of Galen when they taught that the arteries were ducts for the transportation of air were after all very close to a physiological truth. As one passes upward from sea level the reduction in atmospheric pressure soon produces a reduction in partial pressure of oxygen which has real physiological significance. Thus, at 5 000 ft. above sea level the partial pressure of oxygen corresponds to 17.5% of the atmosphere at sea level (instead of the normal 21 per cent). Even at this point a few individuals begin to show an accelerated heart beat. At 10 000 ft. the concentration of oxygen is only 14.2% of a sea-level atmosphere and symptoms are more marked and more general. Beyond 13 000 ft., with concentrations below 12.7%, mountain sickness becomes a serious problem—a problem created entirely by deficiency in oxygen. The gallant struggle to conquer Mt. Everest, which has been followed with such eager interest during the past few years, is first and foremost a struggle against oxygen starvation and cannot be successful unless means are found for transporting oxygen apparatus for the use of the climbers who are to accomplish the last few hundred feet of rock which still tower unconquered into the sky. For the aviator too this problem is of the most pressing import. Bombing and observation planes are able to fly for hours at heights of 12 000 ft. or more and pursuit or battle planes not infrequently reach altitudes of 20 000 ft. The so-called "air staleness" among pilots is merely mountain sickness in a pronounced form, and the studies made by the Medical Research Laboratory of the Air Service at Mineola, N. Y., along lines outlined by the speaker's colleague, Professor Yandell Henderson, have shown how the worst effects of this malady may be avoided by the selection of pilots shown by specially devised tests to be peculiarly resistant to low oxygen pressure.

Chemical Problems of Ventilation

On mountain tops and in the vast spaces of the empyrean where the airman goes, the most serious atmospheric hazard is the lack of oxygen. At the other extreme of human pioneering—in the bowels of the earth—the same danger is met in a different form. In the deep parts of mines, and in old wells, the normal atmosphere may be replaced to so great an extent by carbon dioxide that men entering such places may perish of oxygen starvation. On the surface of the earth itself, however, in the normal haunts of man, the problem of oxygen content need give no concern. Even in the worst ventilated classroom or auditorium or workshop the oxygen in the atmosphere never falls below 20%, on account of leakage through cracks and the rapid diffusion which takes place even through solid walls and ceilings. Lavoisier, as early as 1777, showed by animal experiments that the symptoms experienced in a badly ventilated room could not be attributed to oxygen deficiency. It is only when the partial pressure of oxygen falls from its normal 21% of an atmosphere to a value of 16% or less that important physiological reactions are involved.

Lavoisier himself believed that the evil effects of vitiated air were due to the toxic effects of carbon dioxide, and this view was held by physiologists for about 100 years. It was Pettenkofer in 1863 who first clearly enunciated a third theory, that the influence of bad air was due to the presence of toxic organic substances excreted into the atmosphere from the human body. In his criticisms of the carbon dioxide theory, at least, Pettenkofer has been supported by all subsequent observers. The presence of carbon dioxide is indeed of fundamental importance in relation to human life, as it is the concentration of this gas in the blood which determines the activity of the respiratory mechanism. In the absence of carbon dioxide, breathing would cease and asphyxia result and the increased depth and rate of respiration after vigorous physical exercise is the direct result of increased carbon dioxide in the blood stream. An atmospheric concentration of 2% of this gas causes an automatic increase of about 50% in depth of breathing, just such as occurs with moderate exercise; and in breweries and mines such concentrations are actually borne with no appreciable discomfort. In the worst ventilated rooms carbon-dioxide content rises only from the normal 0.03% to about 0.5% of an atmosphere and such a change as this is well below the threshold of physiological significance.

On the other hand, Pettenkofer's alternative hypothesis of toxic organic substances in respired air has proved as untenable as the carbon-dioxide theory in explanation of the physiological phenomena characteristic of badly ventilated rooms. Revived again and again, by Brown-Sèquard, Weichardt, and other physiologists, the assumption of such organic poisons has repeatedly been disproved by more careful studies. Certain subtle psychological responses to the presence of atmospheric odors will be considered subsequently, but it is clear that the ordinary sensations experienced and the ordinary physiological responses manifested in a badly ventilated room are due neither to reduced oxygen nor to increased carbon dioxide nor to the presence of hypothetical

organic poisons. Human occupancy of a confined space produces five different changes in the atmosphere, namely, decrease of oxygen, increase of carbon dioxide, increase of products of organic decomposition (as evidenced by the "body odor"), increase of temperature, and increase of moisture. The first three having been shown to be inadequate to explain the effects of bad air, we must turn to the last two. As Professor Lee has summarized the situation in epigrammatic form, "the problem of ventilation is physical, not chemical, cutaneous not respiratory."

Thermal Problems of Ventilation

It was Hermans, of Amsterdam, Holland, who, in 1883, first clearly enunciated the theory that the evil effects of bad ventilation were primarily due to overheating and consequent interference with the elimination of heat from the surfaces of the body. This view was confirmed in 1905 and succeeding years by Flügge and his associates at Breslau, Germany, and, later, by Hill and Haldane in England and by Benedict and the New York State Commission on Ventilation in the United States. In one form or another these investigators have repeated a single crucial experiment which may be schematically described as follows: A group of subjects are placed in a closed experimental chamber and kept there while oxygen decreases and carbon dioxide, organic matter, temperature, and humidity increase. They manifest the usual symptoms characteristic of "vitiated" air—headache, general discomfort, lassitude, changes in blood pressure, pulse rate, and the like. The attempt is then made to relieve these symptoms in two alternative ways—by permitting the subjects to breathe chemically pure air (admitted, for example, through a tube from outside), or by lowering the effective temperature of the chamber by cooling coils or the operation of fans, without altering its chemical composition. The first procedure is ineffective, the second completely effective.

It will be noted that the vitally important point in all this is the rate of heat loss from the skin and that this rate of heat loss will depend on the combined influence of three distinct atmospheric factors, temperature, humidity, and air movement. When the temperature is low, heat loss from the body surface is effected chiefly by direct conduction and convection and as moist clothing conducts more readily than dry clothing, moist cool air feels colder than dry cool air. At high temperatures, on the other hand, the body loses heat chiefly by evaporation and as atmospheric moisture hinders this process, moist warm air feels hotter than dry warm air. At temperatures below that of the body, air movement accelerates heat loss and plays such an important rôle that still indoor air at 72° Fahr. may be really "warmer" from a physiological standpoint than a breezy outdoor atmosphere at 90° Fahr.

Recent investigations, particularly those carried on in New York, have made it clear that these thermal problems of ventilation are of the very first importance, and that even slight degrees of overheating may produce far-reaching results. In the first place the studies of the New York State Commission showed that even an atmospheric temperature of 75° Fahr. in still air caused a definite increase in body temperature and heart rate, a marked

decrease in general vasomotor tone, and an increased rate of respiration. In the second place this relatively slight overheating caused a decrease of 15% in the physical work performed by subjects not compelled to maximum effort but stimulated by a moderate cash bonus. The inferences from this fact in regard to the economic losses due to overheated factory workrooms are of far-reaching significance. Finally, the studies showed that in fan-ventilated schoolrooms, at an average temperature of 68.5° Fahr., there was an excess in respiratory illness amounting to 70% and an excess in absence due to such illnesses of 18%, as compared with window-ventilated schoolrooms at an average temperature of 66.5° Fahr.

The conclusions to be drawn from these investigations are of immediate practical importance to ventilating engineers, architects, schoolmen, and legislators. In a large number of States there are now laws which require the positive ventilation of schoolrooms by methods which effect an air change at the rate of 30 cu. ft. per min. These laws have been advocated by the American Society of Heating and Ventilating Engineers in complete good faith on the basis of the older physiological assumption that air vitiation was a chemical condition requiring a definite degree of dilution for its control. The New York State Commission results make it clear that the supply of 30 cu. ft. per min. of air in the schoolroom is not only needless but actually harmful to health and comfort as it almost inevitably leads to objectionable overheating. In the interest of health and of economy these laws should be modified so as to permit of the construction of school buildings ventilated by regulated window inlets and gravity exhaust which the New York studies have shown to be, under some conditions at least, distinctly preferable to the fan-pressure system.

Climate and Season and Disease

The new conceptions of ventilation here outlined make it clear that detrimental air conditions may exist outdoors as well as in and that in midsummer the whole world may be considered as badly ventilated. The prevalence of summer diarrhea of infants has been shown to bear a direct causal relation to summer temperature, and it would be well for architects and engineers to realize that August heat is as harmful as February cold and that provisions for specially cooled rooms and buildings in summer are as logical as those which are now made for heated buildings in winter. The speaker's colleague, Professor Ellsworth Huntington, has shown by exhaustive and carefully controlled statistical studies that the efficiency of factory labor reaches a maximum when the mean temperature for the 24 hours averages about 60° and that the death rate (based on figures for about 9 000 000 deaths) is at a minimum when the mean temperature for the 24 hours is 64° Fahr. and the mean relative humidity is 80 per cent. Professor Huntington points out that a climate which is essentially ideal from the standpoint of moderate temperature and humidity and stimulating variability exists only in Western Europe, in the Northeastern and North-Central United States, in Japan, and in parts of Australasia, and we may be prepared to agree with

him that a favorable climate has been one of the major factors in the development of the dominant civilizations of the world.

The Physiological Effects of Sunlight

The relations between the atmosphere and the human body with respect to oxygen, temperature, and moisture have been reviewed briefly. Of the four primary physiological relationships of the aerial envelope there remains only that of sunlight to be considered.

The value of sunlight as an adjunct to health has been stressed by hygienists since the days of the Greeks. In the medieval code of the School of Salernum prominent place is given to the admonition,

"Let air you breathe be sunny, clear and light,
Free from disease, or cesspool's fetid blight."

Soft coal was introduced into London about the end of the Thirteenth Century and almost at once an agitation against the "smoke nuisance" began, leading even in the reign of Edward I to a prohibition of the use of soft coal during the sessions of Parliament. English authorities have devoted much attention to this problem during the past few years and have demonstrated the astounding fact that between 80 and 400 tons of solid matter per annum is deposited from the air of English cities on every square mile of territory. In Manchester and Leeds, England, and Glasgow, Scotland, it has been shown that the average amount of winter sunlight is diminished about 40% as compared with adjacent rural districts and Besson reports that the smoke of Paris causes a reduction in sunlight of 15 to 25% as far as 10 km. from the city. In this country, the Cleveland, Ohio, Chamber of Commerce has estimated the financial loss due to smoke at $12 per capita per annum.

So far as the effects upon health are concerned, it must be remembered that the whole theory of the beneficial effects of sunlight has rested in the past on a purely empirical basis. Various authors reported statistical studies indicating that the death rate was higher in smoky cities than in rural districts and in the smoky winter season than in summer; but conclusions drawn from such analyses as to the harmful effect of a smoky atmosphere *per se* were clearly fallacious. Too many of what the late George C. Whipple, M. Am. Soc. C. E., has called "concealed classifications" were involved for any sound distinction between the influence of smoke and the influences of urban life or of the winter season as a whole. Even the revival of the cult of Apollo by Rollier and his Swiss colleagues in the treatment of tuberculosis by exposure to sunlight rested on purely clinical observations which were not altogether convincing, in view of the fact that tuberculous patients who live a hygienic life so generally recover whatever other special treatment they receive. Of sound and incontrovertible experimental evidence as to the hygienic and therapeutic value of sunlight there really was none until five years ago. The conscientious teacher of hygiene, when he came to such problems as that of the smoke nuisance, was forced to buttress his case by ingenious hypotheses as to the effect of soot in causing people to keep their windows closed, or in leading them to form habits of personal uncleanness; but he was never quite happy about the matter.

When Huldschinsky in 1919 showed that irradiation with sunlight or with the quartz mercury vapor lamp prevented and cured rickets, a new chapter in physiological science was opened. The work of Hess in New York, and of Park at Baltimore, Md., and New Haven, Conn., has made it clear that rickets can be controlled by two apparently distinct agents, the administration of cod liver oil and irradiation, neither obviously related to the abnormalities of calcium and phosphorus metabolism which characterize the disease in itself.

Now come Steenbock and Black and Hess with the demonstration that foods which do not in themselves possess anti-rachitic value may be endowed with such a value by exposure to ultra-violet light; and finally Kugelmass and McQuarrie with the really epoch-making discovery that a long series of substances curative of rickets actually possess the power, when oxidized, of blackening the photographic plate as ultra-violet rays would do, while substances which do not cure rickets fail to produce this effect. Furthermore, they find that anti-rachitic substances when irradiated give off oxygen, so that the apparently independent action of sunlight and cod liver oil turns out as Park predicted to be truly an interdependent one. When cod liver oil is given to cure rickets we are really administering "bottled sunlight". The possibilities for general physiological theory (in regard to such oxidative processes as those associated with hemoglobin and chlorophyll, for example) which are opened up by this discovery of the relation between oxidation and radiation are no less than astounding; and as light rays influence general body metabolism so profoundly in the case of rickets, it is altogether reasonable to suppose that they may do so in tuberculosis and other conditions.

For the practical hygienist the chief immediate point is that there is now a rational justification for the instinctive belief in the value of sunlight, a new ground for controlling the smoke nuisance, demanding sound building laws, and advocating the outdoor life. The superiority of scientific knowledge over empiricism is well illustrated, however, by the fact that sunlight admitted through glass is robbed of its most valuable radiations and, as Bovie has shown in his studies of diseases of fowls at the University of Maine, at Orono, this problem may perhaps be solved by the use of windows made of fused quartz. Our fathers were right in believing that sunlight was a good thing; how it really acts and how its benefits can be secured most practically we are just beginning to comprehend.

Bacteria in the Air

In addition to the normal and universal constituents of the atmosphere there are certain suspended materials generally present in greater or less amount, and among such suspended particles are living microbes of various types, to which much sanitary importance was attributed in the past. When Lister devised his first antiseptic spray in 1867, it was the microbes in the air which loomed largest in his mind as potential factors in wound infection, and the work of Tyndall and others demonstrated that as far as the decomposition of organic liquids was concerned the germs carried by air might indeed play a predominant rôle.

Since those microbes which are present in air, are largely carried on minute dust particles, it is of interest to note that the bacterial content of dust is a considerable one. Kligler and the speaker have found an average of about 50 000 000 bacteria per gramme in the dust of city streets and between 3 000 000 and 5 000 000 in indoor dusts. Most of these bacteria are of course of harmless saprophytic types, but about 1 in 1 000 of the street dust microbes and 1 in 4 000 of the indoor microbes were of an intestinal type, whereas 1 in 1 000 of the street organisms and 1 in 200 of the indoor organisms were members of the group of *Streptococci* characteristic of the human mouth. From 5 to 20 tubercle bacilli per gramme have been found in the dust from places occupied by tuberculous patients.

Of the dust which may be collected from floors and other surfaces, the amount which actually gets into the atmosphere is after all very small, except when the dust is stirred up by dry sweeping or violent winds. The actual bacterial content of the air is therefore generally low. In one of Pasteur's classic experiments, he opened sterile flasks of putrescible liquids (previously heated and sealed so as to contain a vacuum which would cause an inflow of air when they were opened), in various localities. Of twenty flasks thus exposed to normal country air at Arbois, eight showed the presence of micro-organisms; while of a similar series opened on the slopes of the Lower Jura Mountains only five spoiled; and of a third series exposed on the Mer de Glace one only became infected.

Browne and the speaker have found in country air an average of 56 microbes per cu. ft.; in city streets an average of 72; in the indoor air of offices and schools about 95; and in factories, 113. *Streptococci* characteristic of specific mouth pollution were present to the number of 11 to 12 per 100 cu. ft. in out-door air, 22 per 100 cu. ft. in offices, 30 in schools, and 43 in factories.

Such a bacterial content as this appears to have no important practical significance and as far as the transmission of disease microbes through the general medium of the atmosphere is concerned, epidemiological evidence is overwhelmingly negative. It has been made clear that even the widely distributed pus organisms get into wounds not from the air, but from the skin of the patients or the instrument which produced the wound or other objects which have come in contact with it; while the experience of well managed hospitals has shown that it is possible to care for various communicable diseases in a single open ward without serious danger of cross-infection, if aseptic technique is rigorously maintained.

Within a range of a few feet the direct discharge of mouth spray from an infected person is of course a real and important danger. Trillat, in Paris, has shown that bacteria suspended in moist droplets penetrate a cotton filter far more readily than when aspirated in a dry powder and that bacteria when inhaled by animals in droplets are drawn into the deepest parts of the lungs very quickly, while when borne by dry dust they are almost completely caught and held by the moist mucous membranes of the upper nose and throat, a phenomenon which the speaker suspects may be related to the electrical charges borne by the respective types of particles. The whole problem of droplet infection is, however, more nearly related to contact than to general

atmospheric pollution. The mouth spray is a fine rain which settles quickly to the ground, not a vapor which disseminates itself through the air, and Robinson and the speaker have found that the vast majority of the bacteria discharged in coughing, sneezing, and loud speaking, disappear from the air beyond a radius of a few feet.

Problems of Atmospheric Dust

The microbes of the atmosphere of course constitute only a minute fraction of the suspended matter which it normally carries. Lifeless organic particles and finely divided inorganic matter are present almost everywhere and are made manifest by the reflection of light as the dancing motes in a sunbeam. Such particles play an important part in promoting the formation of fog and rain, serving as nuclei for the condensation of atmospheric moisture; and to the reduction in the amount of aerial dust is due the clearness of the air after a heavy rain. As Tyndall showed in his classic experiments the larger of these particles will disappear so completely from the air in a closed box with glycerine-covered walls that a beam of light passed through the box is entirely invisible. Part of this dust is raised from dry surfaces by the wind like that borne into the City of Pekin, China, from the Gobi Desert. Part comes from volcanic eruptions. The dust discharged during the great eruption of Krakatoa remained for several years in the atmosphere and traveled many times around the globe. Another important fraction of aerial dust is of extra-terrestrial origin because in addition to the 20 000 000 meteorites per day which appear as "shooting stars", finer "mineral particles of foreign source are constantly pouring through our atmosphere in the form of a dry and invisible rain."

The number of dust particles which may be detected in the examination of air depends very largely upon the method of sampling and analysis. Optical methods which depend on the depth of fog produced by condensation of moisture on the dust particles in a vacuum tube may show billions of particles per cubic foot in ordinarily clear air. For practical purposes it seems probable that the more minute of the motes in the sunbeam are of little practical importance and most methods of examination depend on the collection of dust particles by water-spray or by impingement in water or on a vaselined plate and on the counting of the particles under the microscope, a procedure which gives in the main those particles with a diameter between 1 and 10 microns. Counts made with the Palmer water-spray apparatus show less than 10 000 particles per cubic foot (and less than 0.001 mg. per cu. ft.) in country air after a rain and 23 000 particles outside the fifty-eighth floor of the Woolworth Building; as compared with 118 000 particles per cubic foot in the street outside the Woolworth Building and about the same number (100 000) in ordinary indoor air. In dusty factories, on the other hand, the number of dust particles may rise to millions. In an abrasive factory at Niagara Falls the average of nine air samples gave the astounding result of 159 779 000 particles (7.805 mg.) of dust per cubic foot of air.

The influence of atmospheric dust upon health varies even more with the kind than with the gross amount of dust which may be present. As to the

effect of organic dusts little exact and conclusive information is available. Coal dust and cement dust when inhaled in considerable quantities appear quite definitely to favor acute respiratory infections, such as bronchitis and pneumonia, but if anything tend to diminish liability to tuberculosis. Silica dust, on the other hand, has a peculiar and characteristic influence in predisposing the tissues to the invasion of the tubercle bacillus. How far this may be due to the fact that silica particles are less readily eliminated from the lung tissues than carbon particles and, therefore, produce more far-reaching fibrotic changes through their irritating action; how far to some specific influence of silica in attracting or fixing tubercle bacilli in its vicinity; and how far to other factors as yet unrecognized, cannot be stated. The end result, however, is beyond dispute, as is clearly shown by the vital statistics of sand-blasters, granite cutters, polishers, and grinders, and other workers exposed to siliceous dusts. The City of Barre, Vt., in the center of the granite-cutting district, showed for a 10-year period a tuberculosis death rate more than 250% of that of the State of Vermont as a whole. In a certain axe factory in Connecticut, the men employed in grinding and polishing suffered from a tuberculosis mortality more than 1 180% that of their follow employees in the same factory not exposed to silica dust. Seventeen men out of every thousand in this group of grinders and polishers died every year as a direct result of industrial tuberculosis.

It is evident from these facts that the presence of fine particles of silica dust is one of the most deadly characteristics which the atmosphere can possess; and that definite measures for the protection of the worker in dusty trades, by the use of enclosed or moist processes, by the installation of local exhaust ventilation, or by the provision of masks and respirators, is of primary and essential importance.

Industrial Poisons

In addition to these siliceous dusts which so strikingly predispose to tuberculosis, the industrial hygienist must also contend, in certain crafts, with atmospheric dusts and with fumes and gases of a specifically toxic nature. In the State of Ohio, to take only one recently reported body of statistics, there were reported to the State Department of Health during a period of 10 years, 1 295 cases of industrial lead poisoning, and the vast majority of such poisonings are due to the inhalation of lead dust and fumes. In the hospitals of Detroit, Mich., during three years, there were treated 108 cases of lead poisoning, of which 67 occurred in a single factory among a group of men employed in the dry sand-papering of lead paint. The remedy here, as in many other processes, lies in the adoption of methods which will prevent the dissemination of atmospheric dusts of poisonous nature, but where this cannot be accomplished, the protection of the workers by masks and respirators should be enforced.

Lead is still the most important of the purely industrial poisons, but there are many others which affect smaller groups of workers in a more or less intensive degree. Mercury salts which cause the "hatter's shakes", arsenic, and other heavy metals, the oxides of nitrogen which produce acute and often

fatal injuries to the lungs of munition and chemical workers, the irritant halogens, and a whole host of organic poisons, such as anilin and benzine and their derivates, are all common and serious industrial poisons. The increasing use of benzol in industry has attracted special attention during the past few years; a Committee of the National Safety Council has been studying the problem, with the conclusion that the danger from this substance is a real one but that it can be largely controlled by efficient local ventilation.

Of more than purely industrial significance is the menace of carbon monoxide poisoning. Unlike carbon dioxide, this gas is an active poison attacking the red cells of the blood; and it is discharged into the atmosphere under a wide variety of conditions which involve the one common factor of imperfect combustion. In industry, employees about blast furnaces, electric ovens, and similar installations are stricken down in almost instantaneous death when exposed through some accident to a heavy dose of this gas. In the home, fatal cases of carbon monoxide poisoning are increasingly common, due to defective heating fixtures or to the use in small rooms of gas heaters not designed to secure perfect combustion when their radiating surfaces are cold. In the State of Ohio during the winter of 1922-23 there were 113 cases of partial asphyxiation and 64 deaths from carbon monoxide poisoning, 46 of the cases and 41 of the deaths being due to gas-fired room heaters.

Above all, however, it is in connection with the automobile that the danger of carbon monoxide poisoning has become most serious. One can scarcely pick up a paper in winter without reading of accidents due to the liberation of carbon monoxide from engines kept running in closed garages. Furthermore, it seems probable that aside from the acute and fatal cases of poisoning there is a widespread chronic intoxication among garage workers and others exposed to this gas. A recent study made by Ciampolini for the State Department of Labor of New York, showed that of 31 garages, 24 showed carbon monoxide in the air, 17 of them in an amount in excess of 0.1% which is set as a danger limit by competent authorities; while of 42 workers in these garages, who were examined physically, 29 showed evidence of carbon monoxide in their blood and many exhibited definite clinical symptoms of carbon monoxide poisoning. Henderson and Haggard believe that even outdoors dangerous concentration of carbon monoxide may be reached under conditions of crowded street traffic. The remedy suggested by these investigators is the equipment of all closed automobiles with a vertical exhaust, discharging above the roof so as to carry the poisonous gases away from the breathing zone outdoors and to discharge them into the range of roof ventilators in the garage. In view of the seriousness of the hazard involved, this policy deserves and is receiving the very serious consideration of health authorities throughout the country.

Odors and Health

The theory that miasmatic vapors of the atmosphere were the chief causes of epidemic disease dates back to the days when Hippocrates lighted fires in the streets of Athens to purify the air and put a stop to the plague. This view persisted as a dominant factor in medical teaching for 1 500 years, and

when the medical faculty of Paris reported on the epidemic of plague which ravaged that city in 1348, they attributed the disease as Hippocrates did, primarily to malign conjunctions of the planets and, secondarily and immediately, to a corrupted atmosphere. A free translation of one paragraph of this famous document would read somewhat as follows:

"Although there is danger of pestilential sickness from corrupted water and food as is observed in times of famine and drought, yet there is greater danger of sickness from the corruption of the atmosphere. For bad air is more injurious than food or drink on account of the velocity with which it penetrates to heart and lungs with its evil qualities. We believe that the present epidemic or plague arises immediately from air not only qualitatively altered but corrupted in its substance. By this I mean that normal air existing in its clear and pure state cannot decay or become corrupted unless from the admixture of evil vapors.

"Because therefore many corrupt vapors from the aforesaid conjunction from earth and water have been raised up and disseminated through the air by the blasts of the heavy and turbid southerly winds, on account of extraneous humid vapors which they bring or have brought with them, the air itself has become corrupted. Air thus corrupted necessarily penetrating to the heart corrupts the substance of the heart according to its nature, and decays the surrounding tissues in similar manner, finally according to nature extends and corrupts the principle of life. This is the immediate cause of the present epidemic."

Even fifty years ago it was still held that such diseases as typhoid fever and cholera were pythogenic in origin, that is, that their causative miasms were generated by the decomposition of organic filth. Murchison, one of the leading physicians of his time, taught in 1873 that such fevers "may be generated independently of a previous case by fermentation of fœcal, and perhaps other forms of organic matter" and that in these diseases "the poison is not like that of smallpox, given off from the body in a virulent form, but is developed by the decomposition of the excreta after their discharge." Dr. John H. Griscom, of New York, writing in 1854 displays an even more exact knowledge of the etiology of such diseases. He says*, on what authority the speaker knows not:

"Dr. Carmichael Smith discovered that the vapors of nitrous acid neutralize and render harmless the typhus miasm, which he ascertained to be sulphuret of ammonia, and on the utility of this discovery being duly tested and confirmed, a sum of 5 000 pounds was voted to him by the British Parliament, as a national donation."

The development of the science of bacteriology gradually dispelled these miasms which certainly existed as corrupting influences in the thoughts of men even if they did not influence their physical health; and to-day it is known that the communicable diseases are no more influenced by atmospheric vapors than by the conjunctions of the stars. The fear of noxious odors is, however, very deeply implanted in human psychology and even after the germ theory was well established the old terror persisted under a new guise—that of the alleged predisposing influence of organic emanations—morbific matter, anthropotoxin—in the atmosphere. The physiologist, Brown-Sèquard, was perhaps the most famous proponent of this theory but all efforts to demon-

* "The Uses and Abuses of Air," 1854.

strate the presence of subtle organic poisons in air vitiated by organic decomposition have for the present failed.

The ordinary effects of the air of a badly ventilated room, as has been pointed out, have been clearly shown to be due to physical rather than chemical factors. Fortunately, however, we are safeguarded from a too arbitrary and dogmatic dismissal of the whole problem of bad smells to the limbo of chimeras by the experiments of the New York State Commission on Ventilation; and it is always a relief to find at least some experimental justification for widely held beliefs, since empirical opinion is so likely to prove itself in the long run not without justification. These New York studies indicated that the stale air of an occupied room, even when artificially controlled from the standpoint of temperature and humidity, did have two slight but distinctly measurable effects upon human behavior. Subjects exposed to such stale air showed a definite disinclination to physical activity accomplishing 9% less work in stale than in fresh air; and they showed a marked diminution in appetite, the quantity of food eaten at luncheon served in stale air being from 4 to 14% less than in fresh air of the same temperature and humidity. Experiments in the laboratories at Yale University have similarly shown that the growth of young guinea pigs is quite definitely retarded by exposure to the odors from decomposing organic matter.

As to the discomfort and at least minor derangements of health produced by more highly concentrated odors there can of course be no question. The most exhaustive study of this problem with which the speaker is familiar is contained in a "Special Report of the Rhode Island State Board of Health on the Cause, Prevalence and Effect of Offensive Odors in Providence, Cranston, East Providence, and Warwick during 1921." The odors in question were produced by the burning of high sulfur fuel oils and by the distillation and refining of petroleum. Their influence extended for distances of 3 to 4 miles from the plants at which they originated and was felt by a population of 126 000 people. Record was obtained of definite symptoms affecting 96 persons, such as irritation of the throat, suffocation or choking sensation, nausea, headache, dizziness, and malaise, reasonably attributed to the odors in question. Mr. Stephen DeM. Gage, the Chemist and Engineer in charge of this investigation, discusses the situation as follows, in a passage which deserves much wider publicity than that attained by the usual State report:

"When our investigation was first started certain physicians and public health men with whom we discussed the matter expressed the opinion that the subject of offensive odors was not a health matter; that the effect, if any, was purely psychological. This is largely a question of the interpretation placed on the term health. With a very few exceptions the symptoms of the cases cited in the previous pages were temporary and not lasting. But, while the effect lasted, it was very real and in certain cases sufficiently severe to incapacitate the victim and of sufficient duration to interfere seriously with his regular avocation. In other words it reduced his mental and physical efficiency for a greater or less period of time at intervals which were dependent on the frequency of recurrence of the odors. It is well recognized by physiologists that intense and offensive odors may cause reflex actions affecting the nervous, digestive, and the secretory systems. Such reactions frequently

repeated cannot help but have an unfavorable effect on the general health. Even if the effect is psychological rather than physiological, if the effects produced upon the system are the same, the ultimate effect on the health must be the same.

"From the results of our own investigation we know that there are at least 96 persons who are or have been more or less seriously affected by these odors. From physicians have been received reports of 32 persons made ill and of 15 persons suffering from other diseases whose illness has been aggravated and perhaps their chance of recovery lessened from this cause. All or nearly all of these persons show a record of symptoms identical in character with those known to be caused by fumes or vapors of certain substances which from all available evidence are probable constituents of the odors which these persons have been forced to breathe at least a material portion of the time for a period of many months. The consensus of opinion among Rhode Island physicians, as expressed in their replies to our inquiry, is to the effect not only that the course of a number of diseases may be unfavorably affected by certain of the constituents of these odors, but also that the effect of these odors or fumes would be prejudicial to the continued good health of normal persons."

It may be concluded, therefore, that although polluted air does not bear the germs of disease and does not carry with it mysterious and specific organic poisons, an atmosphere laden with offensive odors is not only objectionable on æsthetic and economic grounds, but under certain circumstances may constitute a real menace to the public health.

It is of primary importance, therefore, that sewage and garbage disposal plants, packing houses, and oil refineries should be designed and operated so as to minimize the discharge into the atmosphere of products of organic decomposition or of offensive fumes from the combustion and handling of odoriferous materials. The task is exceedingly difficult when one is dealing with such substances as hydrogen sulfide which the nose can detect when present to the extent of 1 gramme in 1 000 000 000 000 cu. cm. of air, or as mercapton which is detected twenty-five times more readily than hydrogen sulfide. In the selection of processes for the disposal of sewage and garbage the possibility of aerial nuisance must always be a determining factor; and where the production of offensive odors is unavoidable, the possibility of deodorization by the use of chlorine or by some other method should be given the most careful consideration.

The Rôle of the Engineer in Promoting the Purity of the Atmosphere

In bringing this somewhat lengthy dissertation to a close, the speaker would point out that success in the effort to maintain a pure atmosphere under the difficult conditions of urban civilization depends on the co-operative effort of engineering experts of all the various types represented in the Society, and is not merely the affair of the Sanitary Engineering Division alone.

It is for the sanitary engineer to conduct intensive studies of the odor nuisance problem such as Mr. Gage has made at Providence, to determine the source and nature of the odors at work, their range of influence, and their effect upon health. It is primarily for him, also, to see that sewage and garbage plants, which are among the most prolific sources of complaint, are designed and operated with a minimum of resulting nuisance.

For the control of odors from industrial plants, however, the sanitary engineer will often be forced to call in the chemical engineer, either to re-arrange processes so as to diminish odor elimination, or to destroy the odors before they are discharged into the atmosphere by chemical means.

For the protection of the industrial worker against toxic fumes and dust and against the deadly influence of siliceous particles, the ventilating engineer must design special local exhaust systems, and it is to the heating and ventilating engineer—educated in the newer physiology and freed from the fetish of 30 cu. ft. per min.—that the public must look for the maintenance of comfortable air conditions in schools, offices, churches, theaters, and other places of assembly.

The mechanical engineer can help in the task of promoting atmospheric purity by the provision of automatic stokers and smoke consumers. Even the electrical engineer has his physiological functions. The speaker can see no evidence that the ozone he offers as an adjunct to ventilation is of the slightest value; but his ultra-violet rays are indispensable in every well-equipped hospital.

Finally, even the railroad engineer and the highway engineer must come into the picture, for the problem of securing fresh air and sunlight for the dweller in great cities is a problem which can only be solved by intelligent town planning and by the skilful use of transit facilities which shall distribute urban populations over a wide area.

In a dozen different ways a thing so common as "the air we breathe" must be safeguarded and controlled by the watchful hand of applied science. Thus only can truth, which as engineers and scientists we serve, free all mankind from the shackles of preventable disease and death.

DISCUSSION

GEORGE A. SOPER,* M. AM. SOC. C. E.—The speaker feels that he has been on a long journey. From the stellar spaces to the bowels of the earth, from the abrasives factories of Niagara Falls to the fogbound cities of Europe, from the Gobi Desert of Mongolia to the hermetically sealed testing chamber of a New York university, is certainly a great distance. He hopes he has escaped from all the dangers of breathing air which Professor Winslow has told about, but he is not sure.

Carbon monoxide is a subtle poison, and since city dwellers are compelled to breathe it day after day and year after year, there ought to be more certainty as to its effects. The danger, if it is one, is increasing. It is increasing with the size and complexity of urban life. With the growth of traffic and of industry the air is receiving more and more carbon monoxide every day and, with the greater height of buildings, the opportunities for its diffusion and removal are becoming less.

One of the principal sources of carbon monoxide may be mentioned to show how rapidly the increase in this gas is taking place in the city atmosphere. In 1923, the number of motor cars registered in New York, N. Y., was 363 590. In 1924, the number had grown to 440 218. The increase was 21% in this one year. The volume of gasoline consumed by these cars in 1924 has been estimated at 185 181 000 gal.

It may easily be that many persons are suffering from slow poisoning and that effects of which there is as yet no proof are being produced that are decidedly injurious. It is a curious fact that people so seldom attribute to the air the sensations of discomfort, if not of ill health, which they experience from it. They sit in crowded and ill-ventilated rooms, until they get tired, little reasoning that it is the state of the atmosphere which fatigues them.

There can be no disagreement as to the significance of carbon monoxide as a cause of sudden death, when present in sufficient concentration. Dr. Charles Norris, Chief Medical Examiner of the City of New York, in an address read March 25, 1924, before the New York Academy of Medicine, and again before the Annual Meeting of the Police and Fire Surgeons of the City of New York, said:

"Carbon monoxide poisoning is of immense interest to the community, for the reason that it claims yearly, in all modern cities, more deaths than occur from any other one cause (including accidental and suicidal gas asphyxiation), except perhaps, in New York City, the deaths from vehicular accidents."

The speaker has said that people are slow to ascribe to the air about them the discomfort which they feel from it. This is particularly true of carbon monoxide. A person may fall over, gassed to unconsciousness, without ever having realized that anything was the matter with him. He may sit and breathe air which is contaminated with this gas and not be made in the least uncomfortable by it until he starts to walk home in the outer air when the symptoms may attack him with such violence that he is unable to proceed. A motor

* Cons. Engr., Great Neck, N. Y.

idling in a closed garage for 20 min. will produce so much carbon monoxide that a person who is working on the car may suddenly fall, lose his senses and die without ever crying out. Many deaths occur from gas heaters and stoves, which give off carbon monoxide to the atmosphere of sleeping-rooms, the lives of the sleepers passing quietly away without the victims waking up.

Some time ago a family was asphyxiated on the eighth floor of a house from a leak in a pipe in the cellar. Recently, there were two deaths in an apartment house in New York ascribed to a small leak in a main in the street. The speaker has broken down a door and dragged out a man near the point of death from a bathroom in which a gas water heater had produced enough carbon monoxide to overcome him. In none of these instances has there been any reason to suppose that the victims have struggled or made any effort to get better air. The gas has robbed them of the power of doing so.

So much for the poisonings of a tragic character which are due to carbon monoxide. Engineers are not unfamiliar with them, for they occur occasionally in mines, tunnels, and some other works of engineering construction. When these accidents are spoken of, however, the tale is not all told. It is necessary to consider the large amount of poisoning from this gas which does not lead to fatal consequences but produces effects which nevertheless may be harmful. Just what these effects are and how harmful they may be is a question that should be considered.

Carbon monoxide is a practically odorless, tasteless, invisible gas, of almost the same specific gravity as pure atmospheric air. It is discharged from automobiles in large quantities, owing to the incomplete combustion of their gasoline.

Are the poisonous gases diluted sufficiently under the everyday conditions of city life? In answering this question two conditions must be taken account of: First, the state of the general atmosphere of the streets and other places where the gases are encountered, in which diffusion is fairly uniform and complete; and, second, the air close to an automobile before the exhaust gas has had time to become thoroughly mixed with the air about it. All know from experience how unpleasant it is to get a breath of the odorous gases direct from an exhaust. One instinctively stops breathing for an instant in order to avoid it. The concentration in this second case is many times that of the first and is hazardous in the extreme.

The standard adopted for the New York-New Jersey Vehicular Tunnel is 4 parts per 10 000, it being expected that this standard will apply only to passengers making the transit of the tunnel in less than 1 hour and usually in less than ½ hour. Employees who are exposed longer are to be provided with an extra amount of ventilation at their stations.

A word as to the way in which carbon monoxide does injury. As every one knows, oxygen is so necessary to life that to be deprived of it causes instant death. It is absorbed from the atmosphere by the hemoglobin of the blood as it passes through the lungs. Hemoglobin will absorb carbon monoxide also. It has a decided preference for it. It takes up the carbon monoxide three hundred times more readily than it absorbs oxygen. It accumulates it and keeps it for a long time. A person recovering from carbon monoxide poison-

ing gets well very slowly. The gas is not irritating or corrosive. It is obstructive. It keeps the blood from absorbing the amount of oxygen which the person needs.

The intensity of the effects depends not only upon the amount of carbon monoxide in the atmosphere but also upon the length of time that one is exposed to it and upon various other conditions. One person may be much more quickly affected than another. In mine accidents where a number of men are killed, others may extricate themselves from the group and walk away. Long exposure to low concentrations produces worse effects than short exposure to high concentrations, even though the total absorption is the same.

Increased breathing facilitates the absorption, so that walking and other exercise accelerates it. Anything that lowers the physical fitness of a person, as fatigue and overwork, contributes to the harmful effects. Children and persons in ill health are ordinarily the first to be affected.

For the blood to take 60 to 80% of the greatest amount of carbon monoxide which it is capable of absorbing is fatal. To absorb 30 to 40% is to produce severe headache, weakness, dizziness, dimness of vision, nausea, and collapse. To absorb 10 to 20% produces a sense of tightness across the forehead, perhaps a slight headache.

When the concentration of carbon monoxide in the air is from 2 to 3 parts per 10 000, the blood will absorb from 23 to 30% in from 5 to 6 hours. When the concentration is 4 to 6, the percentage becomes 36 to 44 in 4 to 5 hours. When the concentration is 7 to 10, the percentage rises to 47 to 53 in 3 to 4 hours.

In other words, if a person breathes air containing between 2 and 3 parts of carbon monoxide per 10 000 for 5 or 6 hours, he is very likely to have a headache with throbbing of the temples, and long before that he may feel a tightness across the forehead and a slight headache, and the blood vessels of his skin may be somewhat dilated.

Now as to the concentrations of carbon monoxide which are to be met with in city streets.

In 1923, Professors Henderson and Haggard of Yale were employed by the Committee on Public Health of the New York Academy of Medicine to make tests of the amount of carbon monoxide in the air of the streets of New York. This they did, between the middle of July and the following March. The samples were collected into suitable containers, which were carried about in a motor car along the streets.

The investigators showed an inclination, as many visitors do, to remain on Fifth Avenue. They went repeatedly up and down that thoroughfare, once as far north as 135th Street, although it is to be noted that, from 59th to 110th Streets, one side of the Avenue is entirely open to Central Park and the air is better for this reason. Following are some of the results of the analyses. One July afternoon, with light traffic, the carbon monoxide among fourteen samples ranged between 0.1 and 0.64 parts per 10 000. On a rainy day, with light traffic, sixteen samples were taken and had a range between 0.5 and 2.6. On a winter morning, with moderate traffic, twenty-seven samples ranged between 0.2 and 4.6. A series of nineteen samples, with considerable traffic, ranged

between 0.2 and 3.1. On still another day, with moderate traffic, fifteen samples varied between 0.2 and 2.9. The average of these ninety-one samples of air from Fifth Avenue was 1.1 parts of carbon monoxide per 10 000 parts by volume of air.

In various parts of the city, on a clear, cool day with light traffic, samples were collected gradually over a period of 20 min. and ranged between 0.6 and 2.1. Finally, on a very cold, gusty day, seven samples were collected which ranged between 0.65 and 1.5.

The tests were made on samples of air collected at times of moderate traffic and, for the most part, on a broad and open thoroughfare under conditions which may be said to have been, on the whole, favorable to low carbon monoxide concentrations. On every day except the first one, when the traffic was light, the samples contained more carbon monoxide than is safe and some of them so much as to be positively alarming.

The investigations should be repeated on a larger scale, now that the number of automobiles has increased so greatly, and they should include a greater variety of places, times, and concentrations of traffic. Certainly, they should cover times when the traffic is heavy, for this is a very common condition and one to which particular interest attaches. Not only is more carbon monoxide produced then but there are more people in cars and on foot to be affected by it.

Not only the maximum and minimum and average condition of the air but the worst conditions which frequently occur should be known. For example, Sixth Avenue under the elevated railroad in the lower Forties is often filled from curb to curb with cars, either moving slowly or idling. Overhead is the low-lying structure of the elevated railroad to interfere with the diffusion of the exhaust gas to the upper atmosphere.

How much carbon monoxide is present when the avenues are blocked with traffic? How much is present when the blue, oily smoke from the motor cars hangs, a thick haze in the streets and there is no wind to blow it away? What is the concentration when traffic is jammed on the narrow cross streets? What is at the taxi platforms of the railroad stations, when it seems, as it usually does, so stifling?

The information collected by a thorough investigation would apply not only to people temporarily on the streets, important as that would be, but it would have more far-reaching value. It is not to be forgotten that the subways get their air from the streets. In fact, they get it from the surface of the pavement, which is the level at which the automobiles exhaust their gases.

The information would have relation to those who work, many of them for long hours, in the shops on each side of the streets, to the shoppers, and to the large numbers of people on the floors above the street level in the buildings which line the streets. For the shops and the buildings above them get much of their air from the streets and at the level of the front doors and cellar openings. Except in summer and under unusual circumstances at other seasons, the air which gets into the buildings enters, not so much through the windows, as does the light, but at the ground floors and cellar levels. It is heated and rises upward. Studies of the ventilation of tall office buildings of

Manhattan have provided a surprising amount of interesting information upon this subject. As Professor Winslow has pointed out, the proper ventilation of schools and shops and apartment houses and, in fact, all buildings, is not to be accomplished by fans and ducts and dampers, so much as through a better utilization of the natural currents of air which exist or may be brought about under the conditions of actual occupancy. In buildings, more attention must be given to what, out of doors, is called meteorology, and out of doors more attention must be given to what, indoors, is called ventilation. If there is to be good air indoors, there must be good air outdoors. It is of paramount importance that cities should be well ventilated.

In connection with the investigation of the air of streets, a study should be made of the health of the people who spend their working hours there. Traffic officers and the motormen and conductors of busses and trolley cars, although obviously selected as much for their rugged health as for the possession of mental qualities, would afford a profitable field for a carefully made and thorough physiological investigation.

Such an inquiry as is proposed would not be without precedent. Studies of subway air and ventilation were made some years ago at the instance of the Rapid Transit Commission of New York, in which many thousand analyses were made and these were supplemented by thorough examinations of the respiratory apparatus of the motormen and conductors on the trains.

Is the speaker exaggerating the possibility of danger from carbon monoxide in city streets? It is possible that he is. It may be that most people can stand a certain amount of carbon monoxide without much harm, just as they can stand tobacco smoke and, in former times, some stood alcoholic intoxication. Perhaps the only bad effects of carbon monoxide in the city is to make people tire more easily, to be a little less correct in judgment, a trifle less certain in mental and bodily co-ordinations, somewhat more irritable, and a bit more susceptible to accidents and disease. In the aggregate this may or may not be important. It has been suggested that some of the very numerous accidents which occur in the streets may be ascribable to the subtle effects of unsuspected carbon monoxide, but nobody really knows.

A word as to the remedy, if a remedy is required. The speaker thinks the remedy should be left to the Engineering Profession. It is really an engineering question how to make better use of the gasoline and thus reduce the amount of carbon monoxide to a minimum. It is an engineering question how to discharge the spent gases so that they will not be driven into the faces and so into the lungs of drivers of other cars and pedestrians. It has been suggested that motor cars carry stacks and send their exhausts upward, as do locomotives. It has been proposed that absorbing chambers, filled with suitable chemicals, be carried by automobiles, for the purification of the gases which they produce.

It is to be hoped that something better than any of these solutions may be brought forward, for, aside from the question of life and health, an improvement over present conditions would certainly be beneficial from the standpoint of reasonable comfort.

LAWS RELATING TO OBNOXIOUS ODORS

By Irving I. Goldsmith,* Esq.

The problem of safeguarding health and preserving the comfortable enjoyment of property is becoming increasingly complex. While remedies grow more efficient, standards mount higher and new dangers are added by commercial and industrial development and the steady influx of population from rural districts to urban centers. The topic under consideration concerns the contamination of the air. Possibly no single natural right is more closely related to the preservation of health, the enjoyment of life, and the comfortable occupation of property than the privilege to breathe clear, pure, and wholesome air. Although modern medicine and science justify and demand relief from conditions which tend to pollute the air, it was anciently recognized that malodorous fumes and stenches impaired health and disturbed the enjoyment of property. Early legal protection was confined largely to the effect of such contamination upon the enjoyment of property, but as far back as Coke's time, the common law had extended its protection to the public in a limited way.

The law relating to the suppression of dangerous and distasteful fumes and gases is found in that division of substantive law known as "nuisance". According to Blackstone, a nuisance is "anything done to the hurt or annoyance of the lands, tenements or hereditaments of another." The present conception of nuisance is broader, however, and "is anything that works an injury, harm or prejudice to an individual or the public."† Nuisances are generally known as private and public:

"They are private when the injury resulting from them violates only private rights and produces damage to a few persons only; or even to one person only. They are public when they violate public rights, and produce a common injury; when they injure or annoy that portion of the public which necessarily comes in contact with them."

There is a third class called mixed nuisances "which are both public and private in their effects—public, because they violate public rights, and injure many persons, or all the community; and private, in that they also produce special injury to private rights."

Again, there is a classification as to the nature of nuisances:

"First, those which in their nature are nuisances *per se* or are so denounced by the common law or by statute; second, those which in their nature are not nuisances, but may become so by reason of their locality, surroundings, or the manner in which they may be conducted, managed, etc.; third, those which in their nature may be nuisances, but as to which there may be honest differences of opinion in impartial minds. If an instrumentality or condition is a nuisance at all times and under all circumstances, irrespective of location or surroundings, it is said to be a 'nuisance *per se*'."

* Deputy Attorney General, State of New York, Albany, N. Y.

† Definitions taken from "Ruling Case Law," Vol. 20, pp. 380, 383.

These definitions cover the basic law governing nuisances. The rules are of ancient origin in jurisprudence, but they are as responsive to present conditions as they were at the time of their conception. The law is progressive and attunes itself with the onward march of civilization. The uninitiated, the impatient, and the radical frequently dub the law as reactionary; but their judgment is based upon either lack of knowledge or wilful blindness. Legal reasoning does follow established principles and honored precedents, but the decisions of the high Courts are undisputed proof of the flexibility of these dogmas in meeting current needs. The Chief Justice of the great Court of Appeals of New York State has said:*

"I shall follow the thought that administration of the law is a practical matter and that where possible, it must with reasonable flexibility adjust itself to new and changing conditions and, in accordance with recognized principles, must attempt to solve the problems of life in a well-ordered, fair and reasonable way which will secure the approval of well informed and intelligent opinion."

And, pursuing the same subject further, he said:

"In somewhat general terms, we may safely define progressiveness in accordance with generally accepted concepts as a disposition on the part of the Courts toward liberal interpretation of remedial statutes to the end of accomplishing the purposes for which they were enacted; a disposition toward that interpretation, extension, and, if necessary, modification of legal rules and precedents so far as permissible which will secure what the sensible and well informed student would regard as a greater measure of justice between private litigants; and a liberal, but justifiable and faithful, interpretation of Constitutional provisions in the direction of upholding the legislative function to adopt enactments for the greater protection and welfare of the public."

The legal principles governing the regulation and suppression of nuisances from the earliest days of the common law, have constantly yielded to the exigencies of progress, and the limited application to property rights has been developed to cover the broader rights of the individual as typified by the public. The subject assigned to the speaker relates to pollution of the air and this discussion will be confined to those offenses in the category of nuisances which render the air unwholesome and unsanitary and constitute a menace to health and the reasonable and peaceable enjoyment of property. It is evident that in a paper of this character only broad general principles can be considered and the distinctions and differences so common to the law must be passed over with the comment that they exist.

The early cases involving private rights pertained very largely to the noxious odors emanating from pig sties and other animal enclosures, vaults, and privies, and from such commercial enterprises as kilns, smelters, coke ovens, and apothecaries. These structures or trades have not generally been considered nuisances *per se* because they constituted an essential part of domestic life and business activities; but objectional and deleterious odors emanating from these sources have always been held to be actionable and, if sufficiently harmful, subject to injunctive relief in equity. The law in this respect has

* *Cornell Law Quarterly*, Vol. 9, No. 4, p. 371.

been established for centuries and has been particularly well summarized in a leading case of the United States Supreme Court:*

"There is no doubt of the general proposition that a man may do what he will with his own, but his right is subordinate to another, which finds expression in the familiar maxim: *sic utere tuo ut alienum non laedas.* His right to erect what he pleases upon his own land will not justify him in maintaining a nuisance, or in carrying on a business or trade that is offensive to his neighbors. Ever since Aldred's case, 9 Coke, 57, it has been the settled law, both of this country and of England, that a man has no right to maintain a structure upon his own land, which, by reason of disgusting smells, loud or unusual noises, thick smoke, noxious vapors, the jarring of machinery or the unwarrantable collection of flies, renders the occupancy of adjoining property dangerous, intolerable or even uncomfortable to its tenants. No person maintaining such a nuisance can shelter himself behind the sanctity of private property."

Although the growth of community life and the development of industrial activities have created new conditions which often menace the health and comfort of the occupants of adjoining premises, the Courts have continued to extend the rule cited to these situations for the protection of neighboring property and the occupants thereof.

Of course, it must be borne in mind that an owner of land is always entitled to the reasonable use of his premises and if damage results to his neighbor from such use it is not actionable. Probably the contamination of the air by soot and gases resulting from the burning of soft coal presents the most vivid example of the effects of modern industry when conducted in or near a village or city. The New York Courts were called upon to enjoin such a nuisance almost twenty years ago and held that in the case before it the burning of soft coal was not necessary for the practical running of the plant and constituted an unreasonable use of the manufacturer's property.† The facts are interesting in defining the scope of the case. It appears that the plant in question was located on the outskirts of a village of 13 000 inhabitants in a sparsely settled neighborhood, but one suitable for residential purposes. The nearest dwelling was owned and occupied by the plaintiff and was distant 840 ft. When the wind was in the right direction, the soot and gases from the defendant's plant settled upon the premises of the plaintiff, causing discomfort and slight discoloration of the residence property. The proof disclosed that hard coal could be used to operate the plant, although the expense would be greater. Under these circumstances, the Court awarded damages to the plaintiff and enjoined the defendant from further operating its plant with soft coal. This case created wide comment at the time of its determination as the damage proved was quite inconsequential, but it firmly established the rule in New York State that no one may make an unreasonable use of his property to the injury of his neighbor. The Court, in its opinion, discusses private nuisances as follows:

"The law relating to private nuisances is a law of degree and usually turns on the question of fact whether the use is reasonable or not under all

* Camfield *vs.* United States, 167 U. S., 518, 522.

† McCarty *vs.* Natural Carbonic Gas Co., 189 N. Y., 40.

the circumstances. No hard and fast rule controls the subject, for a use that is reasonable under one set of facts would be unreasonable under another. Whether the use of property to carry on a lawful business, which creates smoke or noxious gases in excessive quantities, amounts to a nuisance depends on the facts of each particular case. (21 Am. and Eng. Ency. of Law, 2d ed. 692.) Location, priority of occupation and the fact that the injury is only occasional are not conclusive, but are to be considered in connection with all the evidence and the inference drawn from all the facts proved whether the controlling fact exists that the use is unreasonable. If that fact is found, a nuisance is established and the plaintiff is entitled to relief in some form. Unless the fact is found, or it is an inference of law from other facts found, no nuisance is established, even if the plaintiff shows that he has suffered some damage, annoyance and injury. Those evils are at times incidental to civilized life and the sufferer finds compensation in the arts and agencies of civilized society. What is reasonable is sometimes a question of law and at others a question of fact. When it depends upon an inference from peculiar, numerous or complicated circumstances it is usually a question of fact. Whether the use of property by one person is reasonable, with reference to the comfortable enjoyment of his own property by another, generally depends upon many and varied facts; such as location, nature of the use, character of the neighborhood, extent and frequency of the injury, the effect on the enjoyment of life, health and property and the like."

And, further, referring particularly to the nuisance created by the smoke:

"The defendant's business is lawful and not a nuisance *per se,* although it has been found that as carried on it is a nuisance in fact. The extent more than the nature of the injury, the *quantum,* rather than the *damnum,* constitutes the nuisance. Some smoke is generally created by the natural and ordinary use of land near a village or city, and while this may sometimes be annoying to neighbors it is part of the price paid for living where there are neighbors. But when the smoke is so unusual and excessive as to materially interfere with the ordinary comfort of human existence, the trier of the facts, taking into account all the circumstances, such as public utility, locality, immediate surroundings and the like, may find the use unreasonable. This is not a case where the defendant cannot carry on its business without injury to neighboring property, for all damage can be avoided by the use of hard coal, as is done by one of its competitors in the same kind of business in the same locality, or possibly by the use of some modern appliance such as a smoke consumer, although either would involve an increase in expense. It is better, however, that profits should be somewhat reduced when he did not *come to the nuisance* but was there before. 'The safety of property generally is superior in right to a particular use of a single piece of property by its owner. It renders the enjoyment of all property more secure by preventing such use of one piece by one man as may injure all his neighbors' (Sullivan *vs.* Dunham, 161 N. Y. 290, 300)."

This case has been dealt with at length because it so clearly sets forth the law relating to private nuisance caused by carrying on a lawful business, and also because it deals particularly with the burning of soft coal which undoubtedly constitutes the most pronounced nuisance in populous communities.

Like the law relating to private nuisances, that governing public nuisances has its origin in the common law. Blackstone defines public nuisances as "offenses against the public order or economical regimen of the State, being either the doing of a thing to the annoyance of the King's subjects or the

neglecting to do a thing which the common good requires."* According to current decisions a public nuisance exists whenever a common or public right is invaded.† The annoyance must affect a substantial number of persons in order to constitute it a common or public nuisance.‡ Public nuisances for the most part are concerned with the broader and larger common rights, although frequently a public nuisance may also become a private one when special damage is inflicted upon the individual in the occupation of his premises.§ In illustration, a stable may be so negligently maintained in a well settled neighborhood that the entire community suffers discomfort from the disgusting odors emitted and, at the same time, the occupants of adjacent premises may suffer special damage by being denied the comfortable enjoyment of their property.

A public nuisance, as its character indicates, is indictable‖ and may even be enjoined or abated.¶

Although public nuisances have long been recognized by the common law, it is probably a fair statement that most of the invasions of common rights are characterized by statute or ordinance as public nuisances. This does not signify that statutes and ordinances comprehend all acts which constitute public nuisances, but they usually include those acts which are most likely to impair common rights. Neither does it mean that every act declared by the legislature or municipal government to be a public nuisance will receive that construction when reviewed by the Courts.** Even when legislative or local governing bodies have declared certain acts to be nuisances, such acts must be in fact nuisances known in the law.††

The effect of the legislative or municipal declaration is to eliminate any question of the resulting injury being a common one, but it does not make an unlawful act lawful.‡‡ When the determination rests upon particular facts, and they present a question fairly debatable, the judgment of the legislature will usually be adopted and confirmed.§§

The right to brand certain acts as public nuisances by statute or ordinance rests in the police power of the State. The law is well settled that legislation for the protection of the health, morals, and welfare of the people is a proper exercise of the police power of the State. The validity of such statutes intended to suppress noxious odors was challenged in the famous "Slaughter House Cases" and sustained by the United States Supreme Court.‖‖ The cases merit special comment. In 1899 the Legislature of the State of Louisiana by statute provided that the business of slaughtering all animals in the City

of New Orleans should be confined to certain restricted areas and granted to a particular corporation the exclusive privilege to erect and maintain slaughter houses to carry on this trade and the right to exact fees for this service, prohibiting all others from erecting and maintaining such structures or engaging in such business. The Court affirmed the judgment of the Legislature that the slaughtering of cattle in a great city constituted a public nuisance and that it was a proper exercise of the police power of the State to locate slaughter houses where health and comfort required. A part of the opinion of this Court is illuminating in defining the scope of public nuisances and the inherent power of the sovereign to prohibit them:

"'Unwholesome trades, slaughter houses, operations offensive to the senses, the deposit of powder, the application of steam power to propel cars, the building with combustible materials and the burial of the dead, may all', says Chancellor Kent (2 Commentaries 340), 'be interdicted by law, in the midst of dense masses of population, on the general and rational principle that every person ought so to use his property as not to injure his neighbors; and that private interests must be made subservient to the general interests of the community.' This is called the police power, and it is declared by Chief Justice Shaw (Commonwealth *vs.* Alger, 7 Cushing, 84) that 'it is much easier to perceive and realize the existence and sources of it than to mark its boundaries, or prescribe limits to its exercise. This power is, and must be from its very nature, incapable of any very exact definition or limitation. Upon it depends the security of social order, the life and health of the citizen, the comfort of an existence in a thickly populated community, the enjoyment of private and social life and the beneficial use of property'. 'It extends', says another eminent judge (Thorpe *vs.* Rutland & Burlington R. R. Co., 27 Vermont 149), 'to the protection of the lives, limbs, health, comfort and quiet of all persons and the protection of all property within the State', * * * and persons and property are subjected to all kinds of restraints and burdens in order to secure the general comfort, health and prosperity of the State. Of the perfect right of the Legislature to do this, no question ever was, or, upon acknowledged general principles, ever can be made, so far as natural persons are concerned."

The police power is very broad. It was even held by an Illinois Court and affirmed in the United States Supreme Court* that where a fertilizer plant was established by Act of the General Assembly, and subsequently a community grew up about the plant, that under a village ordinance to suppress the operation of the plant, a bill in equity to prevent the enforcement of the ordinance would be denied. The pecuniary injury which directly resulted to the company from the stoppage of its works was held no bar to the exercise of the police power of the State.

Statutory regulations to prevent nuisances are less common, however, than local ordinances. The answer is obvious. Most cities and villages in their charters are delegated with power to adopt ordinances for the promotion of the health, safety, and welfare of the community. Inasmuch as conditions are so different in each locality the local governing body is better able to appraise the local situation and to make its rules accordingly. Of course, the

* Fertilizing Company *vs.* Hyde Park, 97 U. S. 659.

grant to the municipality is limited by the language of the charter and probably never includes matters affecting State policy.

Neither the State nor the municipality can make an unlawful act lawful by statute or ordinance. Such action may rob the act of its character as a public nuisance, but if injury results to person or property, the act still constitutes a private nuisance. In this connection reference is called to a case wherein a municipality erected a pumping station in a residential locality, burning soft coal to produce power, thereby damaging the plaintiff's residence. The defense asserted that, in establishing the pumping plant and thereafter operating it, the defendant was exercising a governmental function delegated to it by the State, and, therefore, it was not responsible for the misuser of its delegated power. The Appellate Court affirmed a judgment for the plaintiff on the ground that the delegation of authority must be exercised in conformity with private rights, and if their destruction be involved, in such a case, payment must be made.*

The law has also been clearly stated by the nation's highest tribunal:†

"There are many lawful and necessary occupations which, by the odors they engender, or the noise they create, are nuisances when carried on in the heart of a city, such as the slaughtering of cattle, the training of tallow, the burning of lime, and the like. Their presence near one's dwelling-house would often render it unfit for habitation. It is a wise police regulation, essential to the health and comfort of the inhabitants of a city, that they should be carried on outside of its limits. Slaughter-houses, lime-kilns, and tallow-furnaces, are, therefore, generally removed from the occupied parts of a city, or located beyond its limits. No permission given to conduct such an occupation within the limits of a city would exempt the parties from liability for damages occasioned to others, however carefully they might conduct their business."

It is encouraging that the Courts thoroughly recognize the importance of maintaining the air free from pollution. In a renown case the State of Georgia filed a bill in equity in the United States Supreme Court to restrain a corporation maintaining and operating its plant in the State of Tennessee from permitting noxious odors and gases from escaping therefrom and being carried by the winds over the forests, orchards, and crops of Georgia, causing destruction.‡ In granting the desired relief, the Court wrote:

"It is a fair and reasonable demand on the part of a sovereign that the air over its territory should not be polluted on a great scale by sulphurous acid gas, that the forests on its mountains, be they better or worse, and whatever domestic destruction they have suffered, should not be further destroyed or threatened by the act of persons beyond its control, that the crops and orchards on its hills should not be endangered from the same source."

This case is also noteworthy in that it not only recognizes the jurisdiction of the Federal Courts to entertain in equity the petition of a State in its quasi-sovereign capacity, but it establishes a more liberal system of law where the State is a suitor. As to these features of the case, the opinion reads:

* Gordon *vs.* Village of Silver Creek, 127 App. Div. (N. Y.), 888.
† Baltimore & Potomac R. R. Co. *vs.* Fifth Baptist Church, 108 U. S. 317, 334.
‡ Georgia *vs.* Tennessee Copper Co., 206 U. S. 230, 238.

"This is a suit by a State for an injury to it in its capacity of quasi-sovereign. In that capacity the State has an interest independent of and behind the titles of its citizens, in all the earth and air within its domain. It has the last word as to whether its mountains shall be stripped of their forests and its inhabitants shall breathe pure air. It might have to pay individuals before it could utter that word, but with it remains the final power. * * * Some peculiarities necessarily mark a suit of this kind. If the State has a case at all, it is somewhat more certainly entitled to specific relief than a private party might be. It is not lightly to be required to give up quasi-sovereign rights for pay; and apart from the difficulty of valuing such rights in money, if that be its choice it may insist that an infraction of them shall be stopped. The States by entering the Union did not sink to the position of private owners subject to one system of private law. This Court has not quite the same freedom to balance the harm that will be done by an injunction against that of which the plaintiff complains, that it would have in deciding between two subjects of a single political power."

Upon the foregoing authority, the State of New York through the Attorney General in 1916 instituted actions in equity in the Federal Courts to restrain certain corporations operating in Edgewater, N. J., opposite Riverside Drive, New York, N. Y., from discharging over said city, quantities of noisome and disagreeable smoke, fumes, effluvia, and noxious and poisonous vapors and gases, thereby endangering and injuring the comfort and health of its citizens. These actions were the culmination of investigations conducted by the Health Department of New York State, commencing by order of the Governor in 1908 and carried on almost continuously until the beginning of the litigation. The reports rendered upon these investigations disclosed that, because of the fumes and gases cast over from the New Jersey shore, the air was quite generally badly contaminated over that section of New York bounded by Central Park West and the Hudson River and from 72d to 135th Streets. The State of New York thereupon made demand on the State of New Jersey to abate the nuisance, and, no change in conditions being apparent, the bill referred to was filed. The defendants named were the Bulls Ferry Chemical Company and the Corn Products Company, but the Barrett Manufacturing Company, Valvoline Oil Company, and General Chemical Company were also contributing to the nuisance. Definite action on the part of the State of New York, strengthened by the decisions of the United States Supreme Court, produced immediate relief.* The defendants asked for delay in order to make arrangements to abate the nuisance and, within a year, the defendants and the other offenders had remodeled their plants and installed new methods of manufacture and mechanical appliances, so that the nuisance was practically abated. The cases were never tried, but it was the force of the law which actually caused the suppression of this notorious nuisance.

The decisions referred to in this discussion indicate that, except where constitutional or property rights outweigh public necessity, the Courts will prevent the pollution of the air either through the inherent power vested in them under the common law or by virtue of legislative mandate. The law seems

* A contributing cause was Chapter 292, Laws of New York 1917, authorizing the forfeiture of the charter of a domestic corporation and the revocation of the certificate of authority of a foreign corporation to conduct its business in New York State whenever it appears that such corporation is maintaining a nuisance.

to be adequate to protect the public welfare and enjoyment of property, but resort to the Courts for relief appears to be on the wane for the reason that the skill and ingenuity of the Engineering Profession are eliminating the causes which contributed so largely to the undesirable and unhealthy odors and vapors permeating the air in and about cities and villages. Modern sewage disposal, septic closets, garbage incinerators, smoke appliances, refuse reducers, and manufacturing methods designed to absorb or eliminate disgusting and obnoxious smoke, gases, and effluvia are making communities cleaner and healthier and removing any reasonable excuse for pollution of the air. To the engineering fraternity great credit is due, as their solution is the elimination of nuisances fouling the air without injury or harm to any one, whereas the suppression of nuisances through law must necessarily cause inconvenience and expense to the parties besides loss of full exercise of liberty and property rights.

METHODS FOR DETERMINING THE ORIGIN, PREVALENCE, AND EFFECT OF OBNOXIOUS ODORS AND THE EVALUATION OF AN ODOR NUISANCE

By Stephen DeM. Gage,* Esq.

During 1920-21 the writer was commissioned to make an investigation of an alleged nuisance caused by certain oil refining plants in the Metropolitan District of Providence, R. I. In planning this investigation it had to be borne in mind that although it was desirable to obtain as full and complete information as possible on all correlated points, only a very limited appropriation was available for the purpose.

Before starting the investigation, therefore, a search was made through health and sanitary journals and reports to ascertain what methods had been followed in other investigations of similar import. These researches proved of little assistance, however, as descriptions of methods used were omitted from the few reports on odor nuisance investigations that were found. It was necessary, therefore, to rely largely on initiative and to formulate methods of investigation. This paper outlines the writer's idea of how such an investigation should be conducted and points out some of the difficulties which may be met and the manner in which they may be overcome for the guidance of those who may be called upon to conduct a similar investigation.

A complete investigation and report on an odor nuisance should cover the following points:

(1) The origin of the odors, and the cause thereof.
(2) Degree or magnitude of the nuisance. Under this head are included the area and population affected, the frequency and duration of the odor manifestations, and the intensity of the odor at different times and different places.
(3) Effect upon health.
(4) Direct and indirect damage to property.
(5) Remedial measures.

Evaluation of an Odor Nuisance

For purposes of record and also for use in legal proceedings it is desirable to have some means of expressing quantitatively the degree or magnitude of the nuisance caused by odors arising from any specific source. No one will question the fact that an intense odor is more of a nuisance than a mild one. A faint disagreeable odor which persists over considerable periods of time or which is of frequent occurrence must be considered a greater nuisance than a strong odor which occurs only at long intervals, or which lasts only a few minutes at a time. Furthermore, an odor, no matter how offensive it may be, is a nuisance only when there are people to smell it. A strong disagreeable

* Chf. Chemist and San. Engr., Rhode Island State Board of Health, Providence, R. I.

odor which can be smelled by only a small number of people must, therefore, be considered less of a nuisance than an odor of less intensity which spreads out over a large and thickly populated territory. The quantitative expression of the magnitude of the nuisance should therefore include four variables, intensity of odor, frequency of odor, duration of time odor is offensive, and population affected.

If each of these variables be expressed quantitatively, their product should furnish a more representative idea of the magnitude of the nuisance than can be obtained by simply comparing the various figures individually.

The frequency may be represented in such a formula by the number of days the odor occurred in a year or some other stated period. As it is not always convenient to continue odor observations for any fixed period, it is probably better to express frequency as the ratio between the total days when the odor occurred and the total days included in the period of observations.

Duration may readily be represented by the average number of hours per day which the odor lasted.

Population affected might be expressed in direct figures, but in order not to have too many figures in the final result, it is better to express population in thousands.

For odor intensity, there is as yet no generally accepted unit of measurement. This might satisfactorily be expressed as parts per million of hydrogen sulfide or some other substance found to be a common component of a number of different odors, or by a factor representing two or more such substances. This combination of factors may be expressed by the formula:

$$M = \frac{D}{T} \times \frac{H}{T} \times \frac{P}{1\,000} \times I = \frac{D\,H\,P\,I}{1\,000\,T^2}$$

in which,

M = the magnitude of the nuisance;
T = the total days of observation period;
D = the number of days odor was noted;
H = the total hours of odor;
P = the population affected;
I = the average intensity of odor.

In compiling the results obtained in the Providence odor survey, no reliable data on "duration of odor" were available and the records of "intensity of odor" determined by the sense of smell were not considered sufficiently accurate to warrant their being used in a formula in combination with other dissimilar data. It was impossible, therefore, to compute the "magnitude of the nuisance" caused by each source. There were reasonably accurate data on the area and population affected, however, and by combining the daily reports of the special observers with the more or less erratic reports from a considerable number of volunteer observers, fairly representative figures were obtained on frequency of odor. As at least eight odor-producing sources which were causing more or less of a nuisance were under observation, it was desirable to have some method of expressing the relative degree of the nuisance originat-

ing from each source. For this purpose the following simplified formula was used to obtain a semi-quantitative expression of the relative degree of nuisance:

$$N = \frac{P\,D}{100\,T}$$

in which,

N = the degree of nuisance;
P = the population affected;
D = the number of different days on which odor was reported from that source;
T = the total number of days on which odor observations were made.

The value of combining even these incomplete data into a single expression is illustrated by Table 1.

TABLE 1.—Relative Degree of Nuisance Caused in Metropolitan Providence by Odors from Various Sources.

Source of odor.	Total days covered in observation, T.	Number of days odor was observed, D.	Population affected, P.	Relative degree of nuisance, $N = \frac{P\,D}{100\,T}$.
Oil Refinery No. 1	148	53	87 00	283.0
Oil Burning Plant No. 1	158	40	32 650	83.1
Oil Refinery No. 2	121	43	21 200	76.0
Tar Products Manufacturing Plant	158	16	6 800	6.8
Gas-works	148	6	11 100	5.0
Oil Burning Plant No. 2	158	16	2 200	2.2
Slaughter-house	158	6	4 700	1.8
Oil Burning Plant No. 3	158	11	1 850	1.3

Selection of Observers

In determining the source, prevalence, intensity, etc., of an odor nuisance chief reliance should be placed on the observations of trained persons. The reports of complainants are usually so biased that they are likely to be untrustworthy, whereas the reports of volunteer observers are likely to be so erratic or so irregular that no complete record of cause and effect can be deduced from them. Volunteer observers, however, may be used in order to supplement the data obtained by the paid men. In the Providence investigation, complainants and other interested persons were supplied with return envelopes and blank forms on which they were requested to report location, date, and time that odors were prevalent. These reports, although they were of little statistical value, served as a check on the regular observers and were also of considerable assistance in plotting the distribution of odors at certain times.

As the acuteness of the olfactory sense varies widely in different persons, special pains must be taken to insure that reports of different observers are comparable in an investigation of this kind. In selecting observers, care must be taken to obtain men whose sense of smell is reasonably acute, and then to

train all these men to record odors of the same intensity in the same manner. Engaged in this investigation were two men who, through long association, had learned to report odors on waters on the same base. All observers were trained by these men in methods of expressing odor intensity. As the investigation progressed, the work of each observer was checked at intervals by one of these men, and, in addition, two or more observers were occasionally sent out together in order that they might check each other.

Vagaries of Odor Characteristics

In attempting to trace odors back to their source, due regard must be given the fact that there may be a decided change in the characteristics of the odor with varying dilution. This variation in character proved for a time particularly troublesome in the Providence investigation. In one section a distinct odor resembling scorched sugar was at first attributed to a large bakery located near-by, but was eventually proved to be derived from the incomplete combustion of oil high in sulfur at a power plant some distance away. Near their source, these same odors when strong smelled like rotten eggs or hydrogen sulfide, whereas at a little distance they resembled burning rubber. The reason for these varying characteristics could not be determined. Probably these particular odors were a mixture of different substances some of which were more overpowering or had greater carrying properties than others. It is well known that some apparently simple odors change materially with dilution and that a blend may have entirely different properties from any of its components.

Peculiarities of Odor Travel

Knowledge of the conditions affecting odor travel is far from complete and peculiarities will frequently be observed which are difficult or impossible to explain. If there is little or no wind, odors usually travel very slowly from their point of origin. On the other hand a strong wind appears to dissipate them. In the experience of the writer an odor nuisance is most likely to occur under the condition of what are generally known as light airs, that is, at times when the velocity of the wind is between 5 and 15 miles per hour. In the Providence survey, an odor was observed in only one instance when the recorded wind velocity was more than 25 miles per hour, and in only nine instances when the wind velocity was greater than 20 miles per hour. In some instances odors travel high and at other times with apparently similar conditions they may travel low. In one instance an odor was traced from hilltop to hilltop for some distance, but could not be detected in the intervening valleys. In certain instances an odor settled in what was probably an air pocket and remained a source of offense for some time after it had ceased to be produced at its source, this condition generally occurring when there was some fog and little wind. Strong odors were also observed on the wind blowing up certain streets while parallel streets only a block distant were practically free from odor. Such apparent freaks of odor travel may have been caused by differences in air currents or humidity produced by relatively small variations in topographical or other surface conditions. Variations of this kind, especially when they are of regular occurrence, may lead to wide differ-

ences of opinion among residents of different parts of an odor-affected area as to whether a nuisance does or does not exist. For this reason all such peculiarities should be noted in an odor survey together with the concomitant facts by which they may be explained.

Use of Meteorological Records

It may not be out of place to record a word of caution about the use of official Weather Bureau meteorological records. The accuracy of these records cannot be questioned and it is not the purpose of the writer to cast any aspersions upon the men who make the meteorological observations. It must be borne in mind, however, that the stations at which they are obtained are at a specific point usually at an elevation and that the records apply only to conditions at that point.

During the Providence odor survey good use was made of official records of wind direction and velocity in checking up reports of odor at times when the paid observers were not on duty. In many cases, however, the reports of the observers in sections within four or five miles of the Providence Weather Bureau Station were at variance with the official record. The Providence station is on the top of a sixteen-story building in the heart of the city, whereas the observers were on the ground. Under the conditions which prevailed when the odor nuisances were most prevalent, that is, when the wind velocity was low, the ground currents, especially in urban districts, are likely to be very different from those which prevail at an elevation of 100 to 200 ft. The writer has frequently noticed wind blowing from one direction in one street when in another street only a few hundred feet distant the direction of the wind was entirely opposite. In many cases observers in districts three or four miles apart would report wind blowing from diametrically opposite points of the compass. There is no question that air currents on the ground may vary in direction from those which prevail at a slight elevation. It is these ground currents, however, which govern the movements of odors.

Humidity is another factor which undoubtedly affects odor travel and considerable variations in humidity may exist at a time of light airs in sections which are relatively close together. The presence of water surfaces in the vicinity undoubtedly affects not only humidity conditions, but also the direction of ground currents during the night. It is possible that tidal movements may also have more or less effect on these ground currents. In the Providence survey it was observed that the direction of the wind often changed at about the same time that the tide turned.

Determination of Odor Intensity

For the purpose of recording odor intensities in the Providence studies, the terms "very faint", "faint", "distinct", "strong", and "very strong", were used. These terms may be defined as follows: A "very faint" odor is one which would be observed by some persons, but would pass unnoticed by the majority. A "faint odor" would be detected by the majority and would be disagreeable to a few. A "distinct" odor is one which would be distinctly noticeable to

almost everybody and would be disagreeable to the majority. A "strong" odor is one which would be objectionable to practically everybody. A "very strong" odor would be decidedly objectionable to all except those with a defective sense of smell.

Records of odors described in this manner are very useful for comparative purposes, but cannot be readily used as a basis for mathematical expression of odor intensity.

As a matter of convenience odors of water are frequently expressed by the numerals, 1 to 5, inclusive, a "very faint" odor being recorded by the figure, 1, and a "very strong" odor by the figure, 5. For lack of a more accurate method these numbers are sometimes averaged to obtain some idea of the mean odor intensity during a stated period. It is apparent from the results obtained by Allinson and Katz in their studies of stench producers, that the concentration of odor judged by the olfactory senses is not proportionate to the amounts of odoriferous substances actually present in the air at the time. There is, therefore, no real basis for assuming that a "faint" or "No. 2" odor is twice as intense, or that a "distinct" odor is three times as strong as a "very faint" or "No. 1" odor. In fact, there is some basis for the assumption that when dealing with simple odoriferous substances the mathematical ratio between these five degrees of olfactory sensation is geometric rather than arithmetic. When dealing with compound odors caused by two or more substances, however, it is quite probable that these ratios may vary considerably, depending upon the nature of the stench producers present.

There is need for exact analytical methods for determining the amounts of stench-producing substances in air. Unfortunately, the amounts of such substances required to cause offensive odors are extremely small and their detection and accurate measurement require the examination of very large volumes of air. For this reason the collection of samples in bottles or gas bags as is customary for ordinary purposes of gas analysis is not practicable. The practice of drawing or forcing the air through the test solution, as used in some types of air-analysis apparatus, is also impracticable for field work owing to the fact that air movement through the absorbtive medium must proceed very slowly and a rather lengthy stop at each sampling point is thus required when large volumes of air must be examined.

Attempts have been made to adapt to purposes of chemical air analysis the apparatus devised by Palmer of the New York State Ventilation Commission for collecting the dust from considerable volumes of air. In this apparatus the liquid used as an absorbent is broken into a fine spray by the inflowing air and conditions are thus made favorable for absorption of the gaseous ingredients from the air. In operation, the air flow through the absorption bulb is maintained by a small motor-driven fan, measurement of volume being obtained by passing the air through a standard orifice under constant pressure.

The great advantage of this form of apparatus is that large volumes of air can be passed through it in a relatively short time, thereby permitting

the determination of extremely minute quantities of gaseous and other ingredients. Weston used this apparatus in his investigations at Fall River, Mass., and reports that small amounts of H_2S and other sulfides could be determined with reasonable accuracy. The chief objection to the apparatus in its present form is that the motor requires the use of 110-volt current which limits its use to points where connections can be made with the domestic lighting circuit. It has occurred to the writer that if the motor were wound to be operated by current from a storage battery, the apparatus could then be used at any point which could be reached in a motor car, and possibly the battery charge could be maintained from the generator of the starting and lighting system. Weston's assumption was that the foul smell of the odors which he was studying was largely due to hydrogen sulfide or other sulfur compounds. It is quite possible that this assumption may also be true of obnoxious odors from sewage treatment plants and perhaps other sources. There is no reason, however, why many other chemical ingredients of air should not be determined by the use of the Palmer apparatus. Knowledge of the chemistry of odors, particularly those that are obnoxious, is very meager and there is a broad field for research work to determine what chemical substances are present and to provide suitable methods for their estimation. As has already been stated, the measurement of odors by the olfactory sense is far from accurate, and methods for exact measurements of intensity are necessary if odor surveys are to be placed on a definite basis.

Determination of Prevalence of Odors

The determination of the prevalence or frequency of odors in order that the nuisance caused may be evaluated by the formula previously given necessitates that a sufficient number of observers be on duty to cover the affected district at all hours of the day and night. A man in an automobile with windshield and windows open can make odor observations at frequent intervals over a considerable territory. It may be objected that exhaust odors from the automobile may tend to cause errors in the observations, but if the car is driven at a fair rate of speed, the exhaust odors are left so far behind that they have no practical effect. In the Providence investigation, the observers traveled on bicycles in order to avoid this theoretical error, but in a supplementary investigation made by Dr. Chapin, Health Officer of Providence, the use of motor cars was found to be a distinct advantage.

Information as to the prevalence of odors in various parts of the odor-affected districts was derived both from observations made each night by regular employees and from reports sent in from time to time by volunteer observers living in those districts. Whenever possible, the regular employees traced odors which they noted to their source of origin, and from their reports it was possible to determine both the total frequency of odor during the middle night hours, and the relative responsibility of the odor-producing sources. The reports of the volunteer observers served as a check on the reports of the regular observers and also furnished information as to the occurrence of odors at other times than those when the regular observers were on duty. As might be expected, reports from volunteers were received at irregular

intervals when the visitation of odors was especially marked, and except in one or two instances no attempt was made by these observers to keep a complete record of the occurrence or non-occurrence of odor. In many of these reports it was stated that odors came from certain specified sources, although as a rule the volunteer observer did not trace the source of odor. However, the probable source of odor reported by volunteers could frequently be estimated by a study of the direction of the wind at the time and comparison with other contemporary reports. The volunteer reports, therefore, although of relatively small value individually, did furnish collective evidence of the frequency of odors which proved to be of considerable statistical value.

Determination of Affected Area and Population

There are often times when obnoxious odors are much more intense and affect a much wider area than usual and a special effort should be made to determine the spread of odor under the particular conditions of wind and weather which prevail at such times.

In the Providence investigation, a number of special surveys were made to determine the limits of the territory affected by odors at particular times. The method used was to follow the odor in one direction as far as it could be detected and to record this point. The car was then run some distance farther and turned back toward the odor area, and the point at which the odor could again be detected was recorded. After running well into the odor area and recording the odor intensity at various points, another turn was made and the odor limit at another point was determined. This procedure was repeated until a sufficient number of points had been determined to permit the odor-affected area to be plotted accurately on the map, together with data as to odor intensity at various places. By running outside the odor area at frequent intervals the sense of smell of the observers was revivified and the car freed from odors, thus facilitating the determination of the limits of the odor-affected area and the distance of odor travel.

Theoretically, the area which may be affected by odors from any source is a circle the radius of which is the maximum travel distance of the odors from that source. Owing to the effect of prevailing winds, topographical conditions, and other factors which are not clearly understood, odors usually travel farther in certain directions than in others. The map of the area actually affected, therefore, is likely to be irregular in shape, with a large proportion on one side of the odor source. By platting all the locations at which odors have been noted at various times on a map of the affected sections, diagrams can be made showing the total area subject to influence from any source, and this area can then be measured. In computing the extent of such areas, water surfaces should usually be eliminated, because in a study of this kind, it is the land surfaces with which one is principally concerned. If the same territory is subject to visitation of odors from two or more sources, separate plots should be made of the area affected by each odor source. Maps with the affected areas blocked out furnish a picture of the effect of any odor-producing source which can be obtained in no other way,

and are invaluable, both as a matter of record and as evidence in case action through the Courts is necessary.

From a nuisance viewpoint, it is the population of an odor-affected district, rather than the area itself, which is of major importance. There are a number of ways by which the population of such an area can be estimated with reasonable accuracy. When a house-to-house canvass is made for any purpose as part of the investigation, the number of inhabitants in each house should be ascertained and recorded as a basis for a population count. When it is not feasible to obtain a direct population count recourse must be had to estimates. When the area affected is residential, and not too large in size, a count of the number of houses can be made. Two persons, in an automobile, can cover a considerable territory in a few hours counting and recording the number of houses on each side of the various streets. In such a count, the object is to determine the number of families and a two-family house should be counted as two. Even in closely populated tenement or apartment districts, a close count of the number of families can quickly be obtained in this manner. In some cases, the original street by street data obtained in a special census are available, or the local tax assessors have data which can be used. In a good residential district or in a high-class apartment district it is usual to assume that the average family consists of four persons, but in closely built tenement districts this factor should be increased to five, and in densely populated sections occupied largely by people of foreign birth the factor may be six or even more persons per family. In many communities an enumeration of children of school age in each school district is made every year, and knowing the ratio of school children to total population, a fair estimation of the population of any section can be made from such data. In Providence, where the affected areas were large and thickly populated, and where the influence of various odor sources frequently overlapped, the population estimates were based on the counts obtained by enumerators in different districts in the census of 1920. In arriving at these estimates, the odor-affected and the census-enumeration districts were both plotted on the same map. After blocking out territory known to be uninhabitated, the proportionate part of the census district which lay within and without the odor-affected district was then determined with a planimeter and the census population distributed accordingly. The total population of the odor-affected area, obtained by adding the sectional figures as determined by the method described, was then corrected for the presumed increase in population since the census was taken. In this method of computation it was necessary to assume an even distribution of population within the inhabited portions of the border-line enumeration districts, and also that growth of population was the same in all such districts. In a few selected localities the population estimated by this method was checked by a house or family count and the figures obtained by the two methods were found to be in reasonably close agreement.

When the odor-affected area contains factories and large mercantile establishments the employees of which are subjected to the odors during working hours, the average number of such employees should be ascertained and a

correction made in the total population affected. This is contrary to census-enumeration practice in which only resident population is counted in order to avoid duplication. In an odor survey, however, it is probably fair to assume that approximately one-half the employed population lives outside the odor-affected area, but as these people are subjected to the odors during working hours they should be included in the estimate of population affected.

Effect on Health

Although it is generally admitted that chemical fumes emanating from various industrial processes may cause illness and even death, it is a disputed point as to whether offensive odors *per se* can actually be considered unhealthy. Nevertheless, the claim will usually be made by complainants that their health is being unfavorably affected by offensive odors and it may also be claimed that the symptoms of persons ill from other causes are being seriously aggravated as a result of the nuisance and that their recovery is thereby being delayed or prevented. For these reasons, therefore, an investigation of a major odor nuisance cannot be considered complete until all the facts bearing on its possible effect on health have been collected and correlated. This part of the investigation should be carried out by a physician or at least by one who has had sufficient training in physiology and public health to determine to what extent the symptoms of illness are psychological and to what extent they are actually physical.

Information relating to the health phase may be obtained by a house-to-house inquiry throughout the odor-affected district or by inquiry only among persons who are reported to have been made ill. Frequently an inquiry in one family where illness of this kind is reported will bring forth information about members of other families who have been similarly affected. When feasible the house-to-house canvass is preferable as it is thus possible to obtain definite statistics as to the proportion of the population in whom symptoms of illness are being produced. The inquiry among residents should be supplemented by an inquiry among physicians practising in the affected area to obtain all possible information as to the effect of the odors on patients under their care. If by chance there should be a hospital in the odor area, an effort should be made to enlist the aid of the hospital authorities in the investigation to the end that the effect of odor visitations on various patients may be noted and made a part of the case history. In studying the health phase of this question and particularly in making inquiries among both physicians and laymen, it must be constantly kept in mind that definite facts and not opinions are desired and also that to the layman nausea, sick headache, vertigo, malaise, etc., are real illnesses, irrespective of whether the cause is physical or psychological.

Injury to Property

It has long been recognized by the Courts that property damage may be caused by odors or fumes. Injury of this kind may be either direct or indirect. Direct injury to property may result from damage to buildings, household furnishings, etc., or to trees, shrubbery and other vegetation. Indirect injury

may result from the fact that owing to the existence of a nuisance and the feeling of the people that the locality is unhealthy the property becomes less desirable as a residence or work place and its sale value is therefore depreciated. Although direct or indirect property damage is often considered outside the jurisdiction of sanitary authorities, proof of its existence is valuable as an argument to induce the owner of the source from which the odors or fumes originate to take measures to abate the nuisance. In an odor survey, therefore, it is wise to collect and record all obtainable information concerning both direct and indirect injury to property.

When buildings which have been painted with lead or zinc paints are exposed to fumes containing any appreciable amounts of sulfides, discoloration is likely to ensue. This action is usually more rapid on freshly painted surfaces. Household silver, automobile fittings, etc., may also be tarnished by sulfides. Complaints of such troubles, which at first may seem impossible, on investigation will often bring out information of a surprising nature. Information as to damage to paint may also be obtained by inquiry among master painters and paint dealers. Exposure to acid fumes may affect vegetation more or less seriously and also cause rapid deterioration of sheet metal, textile fabrics, paper, etc. Sometimes inquiry among roofers and sheet metal workers will yield information regarding excessive corrosion of metal roofs, conductor pipes, cornices, etc. Damage to trees can readily be detected by inspection in summer, either by discoloration and withering of foliage or by premature falling of the leaves. As not all vegetation is affected alike, care must be used before a report is made that such damage does not exist.

Indirect injury to property by depreciation of value is somewhat more difficult to estimate. When a nuisance has been of long duration, its effect may sometimes be observed by comparison of changes in valuation in property in different sections on the books of the tax assessors. Information about changing property values may often be obtained from real estate brokers. The financial aspect of a major odor nuisance is usually not appreciated either by city and town officials or by the public. As practically the entire revenue of the community is derived from taxes assessed on property, any material reduction in taxable valuation in one section must be compensated either by increased valuation in other sections or by a general increase in the tax rate. Every taxpayer in the community is, therefore, affected irrespective of whether or not he owns property in the nuisance area, and the presentation of the financial evidence of this nature can be used to influence public sentiment outside the odor-affected area in cases when municipal authorities are slow to take necessary action.

Remedies

This paper has dealt only with methods which may be followed in determining the cause, scope, and effect of an odor nuisance with the object of presenting all the facts clearly and forcibly to the Court or other official body which may be called upon to abate the nuisance. In order that such a report may be constructive, rather than destructive, the investigation should also

include a study of the conditions which prevail in the industrial plant or other source where the offensive odors originate, particularly to ascertain whether the emission of odors cannot be eliminated by changes in the processes or in the plant or whether the offensive character of the odors or fumes cannot be overcome by some method of treatment.

The scope of this paper does not include a discussion of methods of odor elimination. Suffice to say in closing, however, that an industry or other source which is the cause of a major odor nuisance is usually also a financial asset to the community in or near which it is located, and although it is not justifiable to consider such a nuisance as a necessary evil, it certainly is not justifiable to close down such a plant when the nuisance may be abated by the application of remedial measures.

ELIMINATION OF ODORS FROM GARBAGE DISPOSAL WORKS

By Samuel A. Greeley,* M. Am. Soc. C. E.

The disposal of garbage is an operation in which an odor hazard must be fairly recognized. Unless garbage disposal works are designed, built, and operated with care, odors may result. In fact, with some methods of disposal, odors are likely to result unless the design and operation are good. In this regard, garbage disposal is somewhat akin to the odor-producing industries such as tanneries, packing houses, glue works, oil refineries, rendering plants, etc. Measures for odor elimination thus become pertinent.

A number of factors influence the general problem of the elimination of odors from garbage disposal works, one of which centers about the environment. In some locations, some odors apparently are not objectionable. In other locations, the same or less intensive odors might cause a nuisance. In recognition of this fact, the zoning map of Kansas City, Mo., indicates areas where odor-producing industries may be located.

Another factor is the cost of operation. Both construction and operation costs may be increased as odors are eliminated. If the disposal is by reduction, rates of drier operation may have to be curtailed and processes adopted for odor elimination which do not produce additional revenue and which add to the cost of disposal. If it is done by incineration, additional fuel, larger capacities, and sturdier construction may be required.

Other factors relate to the many phases of garbage disposal as a municipal enterprise, including group habits and viewpoints, the efficiency of the operating staff, the financial resources and budget allowances, competitive conditions in the field of garbage plant installations, patent limitations, etc. All these factors are closely interwoven. Local considerations are often justly important and cannot be entirely discarded. A helpful perspective may be secured by describing a few actual conditions.

In Rochester, N. Y., a garbage reduction plant of the most approved design as regards odor elimination is operated in a commercial and semi-industrial district near the center of the city. A similar plant was built on Staten Island, New York, in relatively open country, but not far from residential districts. The protests against this plant were sufficiently vigorous practically to force its abandonment shortly after it was built. The City of New York, however, operates an incinerator in a commercial district only a few blocks from residence and business sections. In two or three other cities, garbage reduction works are in such isolated locations that apparently reduction with less odor control and lower operating costs is permissible. Thus, from a practical standpoint, the attitude of the community, the relative economies of near-by or distant location, and the over-all costs of disposal by various processes must be considered and carefully balanced.

* (Pearse, Greeley & Hansen), Chicago, Ill.

Status of Odor Elimination

Relatively little progress in the development of methods for odor elimination can be recorded with tangible results expressed in definite terms. Inside feeding has been developed at hog farms, but capacities and designs are not generally understood and applied; and too little attention has been paid to the sanitary disposal of the unconsumed garbage and the hog manure. Fume-consuming grates have been proposed for incinerators and the danger of low temperatures has been commonly recognized, but many designs fail to consider needed capacities for grates, flues, and other parts of the incinerator under peak conditions. At reduction works, odorous gases have been washed with water and chlorinated, with a reduction of odors, but methods of applying the water and chlorine to secure the best efficiencies need further development.

It is apparent that the subject of odor elimination from garbage disposal needs technical study and development with a fuller realization on the part of those purchasing garbage plants that the odor problem is vastly important and is likely largely to control the capacity, arrangement, and cost of the works under design. In this paper the writer hopes to visualize the subject more clearly than has been done heretofore, to outline its fundamental aspects, to suggest means of odor elimination, and to stimulate further progress.

Fundamental Considerations

The problem of eliminating odors from garbage disposal works should not be entirely confined to methods of elimination after the odors have been produced. It is a fundamental consideration that odors which are difficult and costly to eliminate should be prevented or reduced as much as possible. The old adage as to the value of prevention before cure is true in this case. However, both the prevention and the cure should be studied and a well-balanced procedure developed with due regard to efficiency and cost.

There appears to be no common scale for determining permissible odor and, therefore, the location and environment of a garbage plant may be considered in the general scheme for odor elimination, although they affect the nuisance resulting from the odor rather than the odor itself. For instance, if it should be necessary in a town to burn garbage, night soil, screenings, or other such refuse materials with an additional fuel, it may be said that the elimination of odors bears a major relationship to the temperature of combustion and, therefore, to the quantity and cost of additional fuel. In this case, is it better to locate the plant far afield, involving an additional haulage cost, but a lower fuel cost, permissible through a somewhat lower temperature standard?

Thus, a fundamental consideration is the standard of odor elimination required or desirable in each locality. In a general way and speaking in practical terms, odors should be eliminated; but it is of the utmost importance that the economic and essential relationship be realized between the type of plant, its capacity and arrangement, and its location, on the one hand, and the degree of odor elimination and its cost on the other. A straight Cobwell reduction plant is likely to produce less odors requiring elimination than a

modified Cobwell or Cobwell-Merz plant in which the drier gases are added to those of the reducers, but the straight Cobwell plant is likely to cost more. The cost and efficiency of odor-eliminating devices thus become pertinent.

Terms Used

It is not necessary in this paper to define at length the terms used. The paper relates primarily to odors from garbage works. Other classes of municipal refuse such as ashes, rubbish, manure, street refuse, etc., are included only as they enter the garbage disposal problem. Garbage is here used to mean the animal and vegetable waste matter originating in houses, kitchens, restaurants, and hotels, and includes the natural content of moisture, and generally, also, the tin cans in which portions of the food were originally supplied.

Of the various methods of garbage disposal, special reference will be made to disposal by feeding to hogs, by incineration, and by reduction, as these terms are used in the broader sense to mean the process used rather than a particular patented device or arrangement. Hog-feeding and the reduction method are applicable to garbage only, but most refuse materials may be disposed of by incineration.

Comments on Odors

Garbage odors should be characterized or classified so as best to promote and facilitate a study of their elimination, as follows:

1.—Garbage odors as related to the food materials comprised, such as cinnamon, coffee, lemon, burnt meat, and many others. Such odors are characteristic of fresh garbage and might be termed the "fresh garbage" odors. Their predominance is relatively brief, depending on the condition of the garbage after its house treatment, the frequency of collection, and similar factors.

2.—The odors of decomposition. In warm weather, for instance, moist garbage decomposes quite readily with the production of odors which are more or less of a nuisance depending on the character of decomposition. Garbage which is wrapped and drained in the kitchen or mixed with ashes decomposes more slowly than otherwise. Odors from decomposing garbage may come from dirty collection wagons and disposal works.

3.—The process odors, an expression here used to include those odors which result from the various methods of garbage disposal and at times are more or less characteristic of them. Such odors are the "pig pen" odor, the odor of incomplete combustion, the odor of drier gases, etc.

Among these odors, some may be classed as pleasant and others as offensive. Some will be intermittent and others more or less continuous; and some may be seasonal. The odors of decomposition are, perhaps, likely to be more offensive, but less widely distributed than those from gases discharged from a chimney top.

Although this paper is not on the subject of odors, but rather on their elimination, it should be noted that scientific information about odors, *per se*, is likely to help materially in developing improved methods of odor elimination. Much of interest has been published on the subject of odors proper, such

as the interesting paper* by Louis L. Tribus, M. Am. Soc. C. E., and the several discussions of it. The following quotation† is of interest:

"The common belief that the olfactory stimulus consists of minute material particles suspended in the air current of the olfactory organ is supported by the observation that odors may be carried on the wind in a definite direction many miles. Odors do not emanate from a given center and disperse in all directions as sound and light do. Moreover, many substances, such as arsenic, that are odorless under ordinary circumstances, give out an odor after they have been heated sufficiently to volatilize. The fact, discovered in 1917 by Woodrow and Karpman, that the adaptation time for olfaction—the time needed for an olfactory sensation to wane completely—is directly proportional to the vapor tension of the odorous material shows that olfactory stimulation is due to the activity of gaseous particles. These and other like observations have led to the conclusion, now generally accepted, that the olfactory organs are normally stimulated by material particles, and not by disturbances of a non-material character.

"Some odorous bodies, such as musk, are well known to give out these material particles for a very considerable time without appreciably changing weight. From the standpoint of a receptor this indicates that olfaction is called forth by an infinitesimally small amount of substance, and measurements directed toward testing this question justify the conclusion. These measurements have been made in a variety of ways."

Facts about the chemical and physical characteristics of odors and odor-producing substances, although relatively meager in the garbage field, are, however, of considerable import in a study of odor elimination. Thus, Parker suggests that certain olfactory stimuli are more soluble in oil than in water and that, in fact, solubility in oil may be "of much more significance for olfactory stimulation than solubility in water". This further suggests that "scrubbing" gases from garbage plants with oil as well as water might prove advantageous.

Parker also indicates that olfaction is essentially a chemical process and that some progress has been made in discovering relations between chemical structure and olfactory sensation. Thus, "* * * in a general way types of chemical constitution can be indicated for the six groups of odors that he [Henning] was able to distinguish. * * * In the burnt odors, the ring is smooth as in pyridin, and in the foul odors the ring is fragmentary as in cacodyl". These comments and quotations are stimulating and show the possibilities before engineers in the understanding of the odor-elimination problem.

Sources of Odors in Garbage Works

The sources and causes of odors in garbage works may be related to the several parts of the works as follows:

(*a*).—*The House Treatment.*—Odors may come from accumulations of garbage in the can or house receptacle and from accumulated piles of garbage spilled from the can. In some apartment houses, the garbage is spouted to the ground and these spouts may become foul.

* "Odors and Their Travel Habits," *Transactions*, Am. Soc. C. E., Vol. LXXXV (1922), p. 378.

† "Smell, Taste and Allied Senses in the Vertebrates," by George Howard Parker, 1922, p. 49.

(*b*).—*The Collection.*—If the collection wagons are not cleaned, or are difficult to clean, they may become quite odorous. Leaky and overloaded wagons may spread odor-producing material along the route. A proper covering of collection units is desirable and may be important.

(*c*).—*The Transportation.*—In cases of long haul, the garbage may be transported from a transfer station to the disposal works in scows, freight cars, or large trucks. Poorly designed and maintained transfer stations with inadequate facilities for washing are likely to produce odors. Such conditions may be aggravated if the garbage is not removed from the transfer station frequently.

(*d*).—*The Final Disposal.*—Garbage disposal works may cause odors through design and construction in the first place and neglectful operation in the second place. Such factors as the capacity and general arrangements of the plant are important.

To secure relative freedom from odors, these several sources should be appreciated and operations conducted to prevent odors as described more fully subsequently.

Effect of House Treatment

Local odors may result from poor house treatment and odors may be spread along collection routes if the interval between collections is too long, especially in warm weather. If the house receptacles are not cans with good covers, but are baskets, boxes, or barrels, they may leak and foul the ground on which they stand, or they may overflow, if they are too small. Local odors may result. A good method is to have the garbage drained and wrapped before it is placed in the can, but this method is not generally applicable to disposal by reduction or hog-feeding. It is practiced in Minneapolis, Minn., Milwaukee, Wis., Trenton, N. J., and elsewhere, and it facilitates incineration. In Madison, Wis., the garbage is wrapped by the housekeeper and then unwrapped at the hog farm before feeding, at a cost estimated at $2 500 per year. This, however, may result in a fresher garbage at the hog farm.

Effect of Collection

Unclean garbage wagons will carry odors along their route. Such odors are noticeable 100 ft. or more from the wagons. They can be eliminated by the selection of a type of wagon easily cleaned, with a good cover, and by washing the wagon at regular and sufficiently frequent intervals. A good type of cover is of canvas arched over the top of the wagon and arranged in sections which can be thrown back during filling.

The European practice is to wash the wagons every day and this practice is growing in the United States, particularly during the summer months. Washing the wagons on alternate days will materially reduce odors, but will not eliminate them. With only two washings a week, odors are likely to develop. At Milwaukee, the estimated cost at pre-war prices of having a man scrub wagons with water and a broom was about 4 or 5 cents per wagon.

Odors in the collection wagons and in disposal works will be reduced if the garbage is collected at sufficiently frequent intervals. A common practice

in this country is to collect once a week in winter and twice a week in summer, but this is hardly sufficient, and a collection every other day in summer is often desirable. In some cities, especially in England and Europe, garbage is collected daily at least from the business districts. This is a good practice if the garbage is to be fed to hogs. Additional collections add materially to the cost but they are often justified by the better service to housekeepers. If a collection unit can visit 250 houses in a working day, each unit will serve 750 houses with two collections per week, and with less garbage per collection probably somewhat more than 500 houses with three collections per week. Thus, more units will be required to make the more frequent collections, entailing an increased cost of less than 50% during the period of more frequent collections.

The collection of garbage, ashes, and rubbish mixed is practiced abroad and to some extent in this country. From the standpoint of odor elimination it is a good practice, but it limits disposal to mixed incineration except where sanitary fill may be possible. If dumps for ash disposal are relatively easy of access, mixed collection is likely to cost more than separate collection, because the former requires a more frequent collection of ashes than householders ordinarily require.

Effect of Disposal

Elimination of odors from garbage disposal works centers chiefly about the disposal plants proper. The sources of such odors may be stated as follows:

(*a*).—Odors from the raw garbage and its storage and handling about the plant. If the plant capacities are such that garbage must be stored at the plant for several days during peak seasons, odors will result. The age of the garbage as delivered to the plant also affects the odor situation. Lime, creosote, and other cleansing and deodorizing substances may be used to advantage. Provision should also be made for cleaning and washing the plant.

(*b*).—Odors may come from the processes. Thus, in hog farms, an incomplete disposal of hog manure and unconsumed garbage may cause serious odor troubles. At incinerating plants, incomplete combustion may permit odorous gases to escape from the chimney top. In the reduction process odors may come from the vapors escaping from open grease-skimming tanks, from hot materials when exposed, and from leaks about piping and tanks. Odors may also come from the digester vent gases and from the drier gases.

(*c*).—Some odors may come from the products of disposal, as, for instance, half burned garbage from incinerators delivered to ash dumps; or the accumulation of tankage, tailings, and sewage at a reduction plant.

The extent of odors from garbage disposal works is influenced more than is realized by details of design and construction. In Reduction Plant A, for instance, floors may be of concrete, piping may be easily kept tight, the capacity may be sufficient so that no garbage is held in storage, there may be sufficient driers so that scorching and burning of the garbage is negligible, and the plant as a whole may be kept clean and in good repair. Contrast such a situation with Reduction Plant B, where floors are rough and uneven, where in the summer heavy deliveries of garbage may be stored at the plant for several

days, where inconvenient arrangement renders pipe maintenance difficult, where driers are forced to operate at high temperatures, and where slovenliness prevails. The elimination of residual odors is likely to be much more difficult at Plant B than at Plant A.

Composition of Garbage and the Gases from Disposal

Little appears of record as to the characteristics and quantities of the gas and odor-producing components of garbage. Most of the analytical data relate to the composition of the garbage as regards incineration, reduction, or feeding to hogs. Thus, an average analysis of garbage in Washington, D. C., for 1915 is given in Table 2.

TABLE 2.

Item.	Percentage by weight.
Moisture	73.80
Combustible	22.50
Ash	3.63
Ether extract	5.12
Potash, as K_2O	0.28
Phosphoric acid, as P_2O_5	0.39
Nitrogen	0.71

An average analysis of garbage in New York, N. Y., from dry composite samples taken in 1905 and 1906 is given in Table 3.

TABLE 3.

Item.	Percentage by weight, dry basis.
Carbon	43.10
Hydrogen	6.24
Nitrogen	3.70
Oxygen	27.74
Silica	7.56
Iron oxide and alumina	0.41
Lime	4.26
Magnesia	0.28
Phosphoric acid	1.47
Carbonic acid	0.59
Lead	0.20
Tin	Trace sulfides
Alkalies and undetermined	4.45

Analyses of the products of combustion of mixed refuse incinerators have been made to determine the CO_2 in the chimney gases, but few have been made with garbage alone. Analyses have also been made of gaseous products from garbage reduction plants. The report on the elimination of odors from the Barren Island Disposal Plants (Osborn, 1915), furnishes data for the digester vent gases, as given in Table 4.

In addition, the following constituents were found to be present: Alcohols, acetic acid, fatty acids, fats, essential oils, and aldehydes.

Samples of the drier gases were found to contain 6.2 to 5.1% of carbon dioxide, 12.6 to 14.9% of oxygen, and 2.2 to 1.2% of carbon monoxide. No

sulfur dioxide was found in the drier gases, but acrolein and similar compounds were indicated.

TABLE 4.

Item.	Percentage before entering condenser.	Percentage After Passing Through Condenser.	
		A	B
Carbon dioxide.....	45.2	36.8	6.2
Oxygen.....	10.8	11.8	18.0
Sulfur compounds.....	Present	Present	Present

It is likely that more analytical data would be helpful in approaching the odor problem, and very likely more are of record. However, so few are readily available that the foregoing are given in the hope that more will be published. It should be stated, however, that odors may be produced by very minute quantities which might not be shown by an ordinary analysis.

Incineration of Garbage

Odors from incinerating plants probably arise more often from the storage about the plant and from incomplete combustion. There are two general types of incinerators which, in a general way, embrace the various designs, for example, the "outside storage" and the "inside storage" types.

Outside storage incinerators are a development of the mixed refuse incinerators first studied in detail in this country by J. T. Fetherston, M. Am. Soc. C. E., in connection with the installation of two plants on Staten Island, New York, in 1908 and 1913. A considerable volume of technical information is available relating to the operation of this type of plant when burning a mixture of garbage, ashes, and rubbish, and also, but to a less extent, when burning garbage and rubbish only. Rates of burning per square foot of grate area, draft requirements, flue areas, and heat balances are quite well settled. Thus, odors from incomplete combustion can be generally avoided. The outside storage of the garbage makes careful design and operation necessary if odors from this source are to be avoided.

In plants of the inside storage type, a large part of the garbage is dumped into the furnace from the collection units as delivered. Outside storage at the plant is thus largely eliminated. However, steady uniform combustion is more difficult and lower rates of burning appear to be necessary. In this type of plant, safe maximum loadings have not been so definitely fixed for continuous complete combustion for the various designs.

Fig. 1 shows an estimated quantity of coal required per ton of garbage to maintain a temperature of 1 250° Fahr. In this estimate, the composition of the garbage, of the coal, and of the mixture for the yearly average, are given in Table 5.

Assuming 75% excess air and 20% loss of heat by radiation, this mixture results in a temperature of 1 240° Fahr.

All incinerators should have ample combustion and dust-settling chambers. Lack of such chambers increases the odor hazard and allows dust and sometimes paper to be carried up the stack. The combustion chambers at Milwaukee have capacities equivalent to 15.4 cu. ft. per ton of mixed refuse furnace capacity per 24 hours.

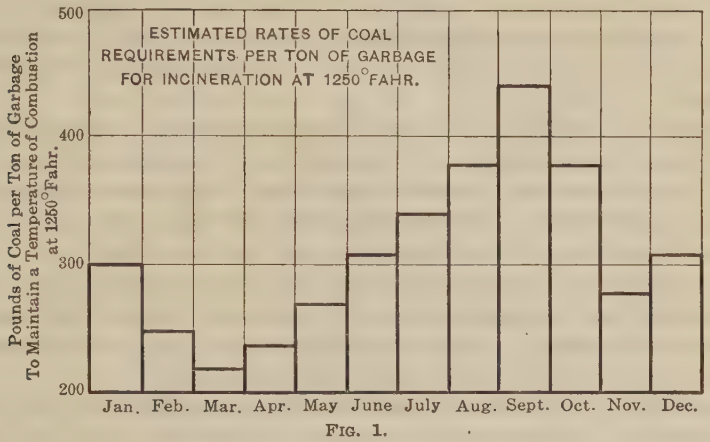

FIG. 1.

Satisfactory incineration over a number of years calls for durable construction with properly designed furnace structures to stand the relatively hard service. With leaky furnace fronts, cracked brick work, and inadequate draft control, cold air enters the furnaces and lowers the effective temperature of combustion.

TABLE 5.

Item.	Garbage.		Coal.		Mixture.	
	Pounds.	Percentage by weight.	Pounds.	Percentage by weight.	Pounds.	Percentage by weight.

Reduction of Garbage

The development of garbage reduction in this country has been influenced by the odor problem as well as by costs of operation and market conditions. Several groups of reduction processes have resulted, among which may be mentioned the following:

(*a*).—The cooking group, in which the garbage is first cooked by steam in digesters and then generally pressed and percolated for the quite complete recovery of grease, the waste liquor being evaporated and added to the tankage. In some plants, the process is limited by omitting gasoline extraction of grease or the evaporation of waste liquids, or both.

(*b*).—The drying group, in which the garbage is first dried and then percolated for grease recovery with a further processing of the residual solids for tankage. In this process, there is no cooking and the digester vent gases are eliminated.

(*c*).—The Cobwell group, in which the entire process is accomplished in closed tanks termed reducers. In the reducers, the garbage is treated with solvent, heated, dewatered, degreased, and dried. The process thus offers a minimum of odor hazard. Recently, the garbage has first been dried to increase the general plant capacities and to reduce net operating costs.

The so-called Morrison process has been adopted at Indianapolis, Ind., and Dayton, Ohio, for the preparation of a stock and poultry food and other products from garbage. It is a cooking process, using a steam-jacketed digester in which cooking, pressing, and drying are done.

At garbage reduction works several relatively well defined sources of odors have been noted. First are the garbage odors arising from the delivery and storage of the garbage. Second are the digester odors which are commonly described as having a caramel or burnt coffee odor. The odor of the digester vent gases is apparent at times and is different from the digester odors. Third are the drier odors resulting from the escaping drier gases. These generally have a sweet burnt vegetable odor with occasional whiffs which are acrid and irritating. By condensation, by washing with water, by heating to a high temperature, by treating with chlorine gas, and by removal of dust, these various odors have at times been largely eliminated.

A comparative analysis of these various reduction processes as they effect odors involves so many local factors that general typical operating schedules are not likely to be helpful. Obviously, a completely developed plant of the cooking type, requires more different, separate operations than one of the drying type. In the former method, the cooked garbage is usually pressed to a cake containing from 55 to 60% of moisture of fairly uniform character, and this cake is passed through driers. Under the latter or drying method, green garbage with an average moisture content about 75% is the material dried. There is, however, a wide range of moisture content in the different particles. Thus, although one process eliminates cooking and pressing, the other calls for heavier work by the driers. Therefore, the economics of operation and the likely success of measures for odor elimination are interrelated.

Factors influencing the costs of disposal are fixed charges which reflect the first cost, labor costs, maintenance costs, net sale prices of grease, and tankage after deducting freight, and the cost of odor elimination. This last factor includes the often considerable increase in first cost due to the type of driers, condensers, and other equipment permissible from an odor standpoint, as well as the cost of odor-eliminating devices.

Digester Operation

The cooking of garbage in digesters generates gases and vapors the treatment of which is important in the control of odors. There are a number of different digesters on the market. Some constitute a vertical cylindrical steel tank, generally lined with vitrified brick, with a false bottom over a drain. In these the garbage is cooked with live steam. The period of cooking varies from season to season with the condition of the garbage and, at times, with its age and state of decomposition. A frequent period is 8 to 10 hours. During cooking the excess steam is vented through small pipes to condensers. Some digesters contain arms or paddles which are rotated to stir the garbage during cooking. Water or waste liquors are added to promote the cooking. Other digesters are steam-jacketed and the heat from the jackets cooks the garbage and may be used to evaporate the liquid contents. In other processes, some of the liquids are pressed out by steam and, in some, the pressed material is partly dried by the heat of the steam in the jacket.

The gases and vapors from the digesters usually pass to condensers, where the steam in the vent gases is condensed and a large part of the gases is absorbed by the water. In some plants, the insoluble gases have been trapped and passed into the boiler furnaces, but it has been found that heating these gases to 2 000° Fahr. does not eliminate them, but makes them more irritating by changing the sulfur compounds to sulfur dioxide. When these gases are first condensed and then burned and discharged at the top of the boiler stack, it is probable that air dilution and dispersion is helpful in reducing the odor trouble. Based on studies by Osborn, Crowe, and Klein, it was concluded that by first heating the insoluble digester vent gases to about 1 200° Fahr. and then passing them through water all odors were eliminated. The extent and character of these odors have not been fully related to the condition of the green garbage and to the schedule of operating the digesters.

Drier Operation

As regards odors, the type and design of drier and the rate of firing and of feeding garbage or press cake are important. With direct heat driers in which the gases and flames of the fire pass directly into the drier, charring or burning of the garbage may result from contact between the intensely hot gases and the partly dried material. This is more likely to occur if the feeding of material into the drier is not uniform and if its distribution in traveling through the drier is uneven. Charring is also more likely to occur if there is a poor adjustment of the fire to the quantity of incoming material and to variations in its moisture content from time to time and throughout the mass.

A commercial rating for a direct heat drier, 5½ ft. in diameter by 40 ft. long, is the evaporation of 4 000 lb. of water per hour. In some garbage reduction plants, rates of direct heat drier operation have been noted as given in Table 6.

As odors such as acrolein (from burned grease) result from burning or charring the garbage, close control of the drier operation is needed. This requires relatively complete combustion in the furnace so that only hot gases reach the drier. The temperature can be controlled to some extent on the way to the drier by air inlets, brick regenerators, and like factors.

TABLE 6.

Plant.	Water evaporated. in pounds per hour.	Dimensions, in feet.	Approximate Moisture Content, Percentage by Weight.	
			Incoming material.	Product.
Pittsburgh, Pa.	3 400	6 by 40	60	10
Chicago, Ill.	6 500	5½ by 40	75	10
New Bedford, Mass.	3 000	5½ by 40	75	35

With indirect heat driers, the chance for burning the garbage by direct contact with the flames is reduced as the flames and hot gases from the furnace pass around the outside of the drier shell with the material on the inside. If, however, bits of grease and other substances stick to the hot shell, they will burn. In some driers, the hot gases pass first around the outside of the drier and then through the inside with the material to be dried. Such driers were recommended for the proposed plant at Cleveland, Ohio, and were rated at an evaporation equivalent to about 8.2 lb. of water per pound of coal, which compares favorably with a direct heat drier.

With steam driers, the moisture is driven off by contact of the material with the shell of the drier (or steam tubes through the drier) heated by live steam. Thus, the chances for burning are practically eliminated unless the dry material ignites. The rate of evaporation, however, is low, as steam driers require about twice as much fuel per pound of water evaporated. Steam driers are, therefore, less often used in garbage reduction plants. However, under some circumstances, it may be preferable to operate at a slower drying rate and a higher cost in order to reduce the odor hazard. In some plants, the garbage or press cake is first dried to about 30% moisture in direct heat driers and then finished in steam driers.

Treatment of Drier Gases

Even with the best of design and operation, it is probable that some odors will result from the driers, and these must be eliminated by special treatment. The most common method is by treatment with water, commonly termed scrubbing. The gases are passed through a masonry structure in which sprays or curtains of water are maintained. A large water surface should be exposed to the gases passing through the scrubber. The sprays of water should condense the steam and absorb the soluble gases and carry both to the sewer. If the velocity of the gases through the scrubber and into the stack is too great, the particles of moisture and some dust will escape at the chimney top, and if insufficient water is used, some of the steam and soluble substances will escape to the atmosphere. Thus, scrubber operation may not be entirely efficient. In scrubber design, the items of temperature, velocity, time, quantity, and exposed surface of water and the general arrangement are pertinent and should be related to the type and rate of operation of the drier.

Dust is probably best removed by sedimentation or centrifuging prior to scrubbing. In some cases, in addition to scrubbing, the drier gases are heated by passing them through the hot gases of a coal, oil, or gas furnace. As a result of the tests at Barren Island, it was stated that "the odor of drier gas can be completely eliminated by heating to a temperature of 1 850° Fahr." Here, again, the cost of heating is pertinent and should be related to the design and operation of the drier and scrubber.

Chlorine gas has been used for the elimination of odors from drier gases under the Henderson-Haggard patents. At New Bedford, Mass., it is estimated that about 1 lb. of chlorine is used per 1 000 000 cu. ft. of drier gases at 100° Fahr. The chlorine is introduced at the entrance to a small scrubber.

Experience with Plant Locations

The selection of sites for garbage disposal works has often been an arduous task, which is apparently more difficult in some cities than in others. Among the more important factors are the following:

(*a*).—The occupancy and use of adjacent areas. Unoccupied and unused areas do not suffer immediate damage from odor-producing industries. Residential districts where people spend their leisure hours and where children are growing up are probably the least desirable districts for locating garbage plants.

(*b*).—The type of disposal plant and the character of its design and construction. The details of the plant may properly be related to its location with due regard to future property developments and plant additions.

(*c*).—The distance to which odors are likely to travel. Odors from digesters and driers in garbage reduction works have been detected at distances of several miles.

A record of plant locations showing the distance from the city hall to the disposal works is given in Table 7. These distances range from a few hundred feet to 50 miles. Some engineers are of the opinion that plants should be located far afield where odor elimination is not required. Others feel that garbage should be disposed of in the community which produces it and in such a manner as to eliminate odors.

General Summary

In odor elimination, attention to detail is the secret of success. Thus, plant upkeep and cleanliness are of great importance. It seems almost axiomatic and certainly it is common sense, that a clean garbage plant tends to eliminate odors as compared with a dirty one; and yet the condition of garbage disposal plants covers a wide range from very dirty to clean. If plant operators would realize that clean means clean and that there is no compromise with dirt, much odor trouble would be eliminated. Having these points in mind, the following considerations will be helpful in odor elimination:

(*a*).—There should, without doubt, be a good general plan for handling garbage covering the house treatment, the collection, and the final disposal. This will result in a fresher garbage at the disposal works.

(*b*).—As part of the general plan, good house treatment should be developed and the collection frequency oriented to the method of disposal and the location of the disposal plant as well as to the convenience of the householders.

TABLE 7.—DATA RELATING TO THE LOCATION OF INCINERATORS, NOVEMBER, 1924.

NOTE.—G = Garbage; R = Rubbish; A = Ashes.
* Discontinued.

(*c*).—Collection wagons should be regularly cleaned to eliminate odors and to reduce the chances of receiving decomposed garbage at the plant.

(*d*).—Garbage disposal works should be built on suitably chosen sites with reference to the character of disposal works and the over-all costs of garbage collection and disposal.

(*e*).—Of particular importance is the capacity of the garbage disposal plant. No garbage plant should be subject to serious overload when garbage collections are heavy, if odors are to be eliminated. This is a real factor too often not given serious and definite consideration.

(*f*).—Following a good general plan, clean operation and ample real capacity of disposal works suitably located, there should be added proper devices for the elimination of residual odors, including combustion and dust removal chambers at incinerators and scrubbers, condensers, burners, chlorinators, etc., at reduction works.

To secure these various measures for odor elimination properly calls for the best of technical engineering effort. To facilitate this work many more accurate data, carefully taken and recorded, should be made available on rates and results of operation for all the various devices. However, with proper

effort, a practical elimination of odors from garbage disposal works can and should be expected.

Tables 8 and 9 give data relating to garbage reduction plants and garbage hog farms, respectively.

CONTROL OF ODORS FROM SEWAGE TREATMENT PLANTS

By John F. Skinner,* M. Am. Soc. C. E.

Synopsis

A study of this subject presupposes a knowledge of the general subject of odors, their nature, production, and means of transport. The writer has had no opportunity for experimental work and, therefore, can treat the subject only in the most general manner. A line of research, however, is suggested which may produce results.

The subject has been studied under the following heads:

Character of Odors,
Source of Odors,
Control of the Production of Odors,
Control of the Escape of Odors,
Conclusions.

General

Sewage, at best, is water-carried filth, the wastes from the population and culinary and industrial processes. Such material may give off odor, usually unpleasant *per se* and often reminiscent of its source.

A sewage treatment plant handling such wastes may be expected to make its presence known in the immediate neighborhood through the sense of smell, but the necessity of dealing promptly, effectively, and continuously with such matter demands considerable tolerance. Efforts should be directed toward minimizing discomfort, nuisance, and damage, by control of the operating process, by the design of the plant, and by its location. Wherever possible, it should be isolated at a distance from occupied territory and the frequency, direction, and intensity of prevailing winds should also be considered. It should be surrounded by a wide area under municipal ownership or control and preferably be masked or screened by vegetation.

Character of Odors

Just as the odor of fresh feces varies with the food and the condition of the individual's digestion, so when the putrefactive process is continued at a sewage treatment plant, odors will vary with the character and condition of the influent sewage and with the regimen of the continuing processes of bio-chemical change and digestion throughout the plant.

The principal gases given off by putrefying sewage are methane, carbon dioxide, and hydrogen sulfide. Only the latter possesses appreciable odor. All of them, however, may act as carriers of other odorous material. As an ex-

* Cons. Engr.; Deputy City Engr., Rochester, N. Y.

ample of this transporting power of gases, pure carbon disulfide has a rather pleasant ethereal odor, but the commercial article carries impurities that give it its well-known smell which is exceedingly disagreeable.

Water vapor may carry gases and other products of the decomposition of organic matter in solution or it may transport such products in colloid form, or in the form of finely divided suspended solids. If these malodorous particles reach human olfactories the fact of the existence of odors is at once established.

Another source of odor is the presence of moulds which reside and grow on walls, floors, hand railings, and all exposed surfaces in the immediate neighborhood of the works. These are readily transmitted by contact with the flesh or clothing. If one touches such surfaces, his hands or gloves will have a noticeable and disagreeable odor for some time thereafter.

Source of Odors

The odor of fresh sewage, when not confined and when flowing tranquilly in channels and tanks, or when remaining quiescent in tanks, is not particularly offensive, except to the hypersensitive. As such sewage becomes older, its odor is more pronounced and its condition passes on through the stale to the septic state, when gas can be seen to bubble from the surface and an odor of hydrogen sulfide may be perceptible and also an odor often described as a "sweet-sickish smell." If sewage is confined, as when it flows through an illy-ventilated sewer or chamber, the air may become very foul.

When the influent sewage flows rapidly over steps or down an incline where the smooth flow is broken by baffles—as is or was the case where lime is mixed with the sewage at Worcester, Mass.—in advance of the chemical precipitation tanks, the odors liberated are very strong. A decided cessation or reduction in intensity of odor is observed at this station as one proceeds along the walk between the tanks, but it again becomes intense on going back to the vicinity of the lime mixer.

Trash from coarse racks, if not complicated by the presence of offal or dead animals, can ordinarily be removed, and disinfected, burned, dried, or covered before foul odors are noticeable.

Detritus or grit from properly operating grit chambers does not emit unpleasant odors, as it contains little putrescible matter. If, however, sludge is allowed to collect in such chambers and remain and become septic, it may give rise to smells.

Fine racks and screens which intercept feces, or places where feces are present in large quantities floating in the screen chamber or accumulated in piles, may become offensive, as noticed in the screen house at Baltimore, Md. If such material arrives at the plant already comminuted, or if visible pieces are so few that it is practicable to break them with a hose stream and pass the fragments on with the effluent, the remaining screenings may vary from washed out garbage and offal to non-putrescible detritus and will only be seriously offensive if not promptly removed and disinfected, burned, dried, or covered.

The odor from sewage in a properly operated Imhoff sedimentation chamber is, as described, dependent on the freshness of the sewage. In a septic tank, however, where the sewage is generally older and where there is a mass of undigested sludge, both below the surface in the tank and floating on the liquid, there is usually a more disagreeable odor from the undigested sludge. This condition is best met by covering the tanks. When sludge is placed in tanks for separate digestion, the odor is more intense and becomes nauseating to many.

The effluent of an Imhoff tank when sprayed upon a sprinkling filter will be more or less odorous, depending on whether it is stale or fresh, concentrated or dilute. It may also be affected by the character of the raw sewage and by the thoroughness of the preliminary operations.

When the sprinklers are in display the odor is noticeable to the leeward, as might be expected. When the sprinklers are at rest and the bed is in good condition little odor is noticeable if sufficient sedimentation has been previously accomplished. If, however, proper sedimentation has not been performed, fragments of putrescible matter of considerable size may lodge on the surface of the bed and form accumulations which will putrefy and give off odors. With proper preliminary sedimentation, the smaller sized particles of suspended matter will pass through and below the surface of the bed and the air entrained by the falling drops will carry down any odors given off by such particles. Moreover, such particles themselves will be washed down into and through the bed.

In the activated sludge process, little odor is occasioned by the aeration tanks. In the direct oxidation process, as the electrolytic tanks are kept closed, little odor may be anticipated except at the screening plant, for the sewage before passing into the sedimentation tanks has been treated with an excess of lime, which also prevents odors from being given off by the sludge.

Thoroughly oxidized effluent from a sprinkling filter and in a final settling basin has no appreciable odor, but the secondary sludge when occasionally removed and allowed to stand until the larvæ and worms contained therein have died and their bodies have putrefied, is sometimes quite offensive for a few days. It has an odor similar to that of a bait box of fish worms which has been neglected until the worms have died from exposure to the sun and lack of nourishment.

Well digested sludge has a not unpleasant musty odor which does not travel far. Some describe it as a "choky odor," or as if it were occasioned by a fine dust.

Control of the Production of Odors

Screenings should be removed promptly and covered with earth. The value of composted screenings as a fertilizer has been suggested. A continuous belt-conveyor has been used at the Irondequoit Treatment Plant at Rochester, N. Y., since 1917 for removing the product of four 12-ft. Riensch-Wurl screens. The belt dumps the screenings into an industrial car which is hauled out when full. The cleanest method of removal is probably by pneumatic conveyor. By this method the screenings are least exposed to the air and to flies.

The writer has a plan for a plant to be constructed in which the only treatment of the sanitary sewage will be multiple screening. It is proposed, after passing coarse racks, to screen the fresh sewage twice through openings of diminishing size and then to convey the screenings, including feces, and grit if any, to the top of a closed silo tank for storage. They will later be discharged from the bottom of the tank into farmers' trucks when required.

Raw sewage and sewage in tanks and channels should be screened or skimmed so that no floating material will be present to putrefy on the surface. Bio-chemical changes in the sewage solids can best take place under water for gas rising through the water will be washed and partly dissolved so that less will be sent abroad into the atmosphere.

If the design of the channels is such that sewage will flow smoothly and not be broken up and vaporized, considerable odor will be avoided. If the design allows spray to be blown into the air, it may be condensed by providing a covering on which the spray may impinge.

Sprinkling filters have been rejected for some exposed locations near dwellings, and contact beds have been constructed rather than the sprinkling filters, because of the fear of odors to the lee of the filters. In such situations, advantage might be taken of the economy of the trickling filter over the contact bed by adopting a dripping distributor in place of the usual sprinklers which toss the spray into the air and thus furnish the greatest cause for complaint as to odors. Wherever possible a location should be sought which is not exposed to winds which may blow odors or flies to a distance. Sludge is more or less offensive as it is less or more thoroughly digested.

Separate sludge digestion tanks have been operated experimentally with a layer of oil to keep air from the surface and solids from exposure on the surfaces. The experiments have not yet been conclusive. As a general proposition, sludge digested under water is less productive of odors than when exposed above water.

Sludge cake from the pressing of undigested sludge is likely to be offensive, especially in warm moist weather. It may be covered with earth or ashes. Digested sludge is inoffensive and does not attract flies.

Lagooning undigested sludge is likely to produce odors, for either scum may form, or there may be insufficient water to cover the sludge which will then putrefy and give off odors.

In general, lagooning should only be adopted in winter or in remote locations where no nuisance will be occasioned to neighbors. Secondary sludge, following sprinkling filters, may be pumped into tanks for digestion, or removed when the weather is best for its disposal by lagooning.

Control of the Escape of Odors

Assuming that certain odors will be produced in a sewage disposal plant engineers are confronted with the problem of preventing their escape from the plant to the surrounding atmosphere at such intensity and with such frequency as to constitute a nuisance to persons residing in or passing through adjacent territory.

If it is assumed that odors are volatile emanations, gases, colloids, liquids, or finely divided solids which reach human olfactories, this part of the study must be directed to the means by which these attenuated gases or minute particles move, what gives direction to their motion, and what effects their intensity as observed odors, in various localities.

The elements which at once suggest themselves are:

(*a*) Diffusion of gases and vapors in still air.
(*b*) Relative temperatures of air, sewage, gas, and vapor (convection).
(*c*) Moisture and vapor tension of the atmosphere.
(*d*) Wind direction and intensity.
(*e*) Topography, elevation, and exposure.
(*f*) Screens, natural and artificial.
(*g*) Mingling of other more pleasant odors.
(*h*) Psychic considerations.

(*a*).—If the air is perfectly quiet and there are no disturbing temperature conditions, a gas or a vapor carrying odors may diffuse equally in all directions in the atmosphere, and its intensity will be inversely as the cube of the distance from its source; hence the odor will not travel far.

(*b*).—If, however, the sewage and the gas or vapor emitted by it is warmer than the surrounding air (a condition which may obtain in quiet winter weather), the warm gas or vapor will rise through the cooler and denser atmosphere until the odor-bearing gas or vapor has cooled to the temperature of the surrounding air. During this time diffusion has been taking place into the atmosphere so that one may assume an odoriferous column expanding upward in the shape of a plume, denser at the center than at the periphery and similar in form to the steam cloud above a volcano; not much odor would cause complaint under these conditions.

If, however, the air is warmer than the sewage, as on a summer day, the gas and vapor given off will diffuse into the atmosphere relatively near the ground and only rise and disperse when it has attained the temperature of the air.

The two opposite conditions of temperature just cited may account, in part, for the more intense odor near the disposal plant in summer than in winter, although doubtless there is the further explanation that more active decomposition is taking place in summer than in winter and greater quantities of gas are liberated during the summer.

There is also the case of the cool summer night when the sewage may be warmer than the denser air and warm enough for the maximum of bio-chemical activity. Being slightly warmer than the air, odoriferous gases will rise to some height, but possibly not far enough to be diffused in the upper air as described for quiet winter weather conditions. With a gentle breeze, these summer nights are often made unpleasant at some distance from the disposal plant, for windows are open and residents may be awakened by an unusual and nauseating odor and have their attention concentrated on this manifestation.

(*c*).—If the air is dry it will avidly take up vapor and as it is no respecter of odors, it will take the pleasant and the unpleasant alike. Winds may carry

these odors to considerable distance. With moist air, however, near the dew point or when rain is falling, sewage vapors will not be taken up and only gases will be transmitted which are being given off so voluminously that they are not entirely absorbed by the rain or atmospheric vapor.

(*d*).—The condition of absolute quiet is so rare as to be almost theoretical, for there is generally some wind movement, be it ever so slight.

A strong wind will usually dilute the odors to so great an extent that they become negligible at a short distance from the disposal plant.

A gentle breeze, however, wafts the odor cloud bodily to leeward before it has become sufficiently attenuated by diffusion to destroy its unpleasant character. This condition is more noticeable in summer when the disposal plant processes are most active and when, as already mentioned, windows are open. This indicates the advisability of not placing a plant to the windward of a summer population.

(*e*).—If the plant is in a protected valley, or one surrounded on the windward side by woods or high hills, the probability of blowing odors from it is considerably reduced.

(*f*).—Screens of natural forest trees not only prevent access of the winds which transport odors, but both forest trees and artificial plantings of trees and shrubs by means of their moist leaves furnish surfaces on which odoriferous gases and vapors may be condensed or absorbed.

(*g*).—If trees and shrubs which give off pleasant odors are planted about the premises in masses sufficient to affect the atmosphere, they will be noticed at times for their beauty and for their pleasant odors and at other times will serve to disguise unpleasant odors by their presence.

(*h*).—Out of sight is out of mind in sewage plants as in other things. Some citizens who see scum on a river at a distance will think they smell it, when in fact the scum and the stream may be odorless.

Neat and artistic planting about the station where it must be exposed, and screens of trees or shrubbery to hide it if possible, do much to prevent imaginary odors from causing annoyance. The nerve sensation called smell may be forgotten if other interests are paramount.

Conclusions

The sewage disposal plant should be designed liberally so that it will not be overloaded. It should be located in a protected and isolated spot. It should be operated to avoid uncovered, decomposing, solid matter and the walls and floors should be kept clean and washed down at least daily. Splashing and the needless production of vapors should be avoided if possible. The plant should be screened from view when practicable and visible parts should be made attractive by means of trees and flowering shrubs. Keep the sewage treatment plant away from the public and keep the public away from it, especially when it is not functioning properly. These measures will mitigate if not entirely prevent the escape of odors from a plant to the surrounding territory.

A suggested line of research is as follows: As exceedingly minute portions of a substance are carried in the air and constitute odors and as bacteria

exist in earth, in sewage, and in the air close above a sewage plant, may it not be conceived that the putrefactive odors which differ from pure gaseous odors are in part, at least, due to the presence of these bacteria in the air?

If this is true, will not the destruction of these bacteria result in the diminution of the odor? Chlorine, the best known disinfectant, would have to be distributed and released continuously in order to be effective, and moreover it would add an odor of its own.

It would seem that engineers might profitably, first, seek for some type of gaseous disinfectant which would be pleasant, or better still, odorless; and, second, devise means for its economical application at the sources of odors in the various parts of a plant.

THE DETECTION AND ELIMINATION OF ODORS FROM OIL REFINERIES

By Robert Spurr Weston,* M. Am. Soc. C. E.

In a commercial or practical sense, the word, petroleum, applies to natural, liquid hydro-carbons which, from a scientific standpoint, are not strictly liquid, but are mixtures of gases, liquids, and colloidally suspended solids.

Shortly after its discovery, the chief use of petroleum was in the preparation of illuminating oil. Following this occurred the development of petroleum lubricants which were found to be superior to the animal and vegetable fats and oils previously used. However, it is chiefly because of the development of the internal combustion engine and the increased use of oil as fuel that the petroleum industry has become so extensive. It is estimated that there are about 16 000 000 automobiles in use in the United States at present (January, 1925), and the number of Diesel, gasoline, and other motors of this general type is increasing for use on land and water, and the high prices of coal and labor have furthered the use of oil for fuel.

The world's production of petroleum from 1919 to 1923 was as follows:

Year.	Total Number of Barrels.
1919	558 892 000
1920	700 902 700
1921	762 241 000
1922	854 809 000
1923	1 010 995 000

Of the total petroleum produced, more than 60% came from the United States, and more than 90% from the United States and Mexico. The production of petroleum in Mexico is declining, but the loss is likely to be greatly compensated by increased production in Venezuela where extensive fields are being exploited.

With this extensive and increasing production of petroleum, it is not surprising that there has been a great increase in the number of refineries throughout the world. Most of the refineries in the United States are situated along an arc drawn from Texas to Massachusetts, in California, and in Wyoming. Until recently there were no refineries in New England, but in the past few years several large installations have been made in the vicinity of Narragansett Bay and Boston Harbor. The introduction of this new industry in thickly settled regions where the people are jealous of the purity of the atmosphere and the cleanliness of the shore waters, has created new sanitary and æsthetic problems.

The use of petroleum in the various grades is growing and has become general rather than local. Therefore, it must be expected that refineries, which have increased from 176 in 1914 to more than 500 in 1924, will be

* Cons. Engr. (Weston & Sampson), Boston, Mass.

located where economic conditions necessitate. Consequently, sanitary engineers must assist in making these plants inoffensive and thus contribute to the prosperity of these localities with the minimal impairment of a healthful and salubrious environment.

There are now three large oil refineries in Massachusetts and two in Rhode Island, and it is in these States that vigorous complaints regarding odors have arisen.

The crude petroleum oils differ greatly in composition, specific gravity, and viscosity, but the property that most concerns sanitary engineers is the sulfur content, which varies from less than 0.1% in Pennsylvania oils through less than 0.5% for Mid-Continent oils, to less than 3.0% for Wyoming oils, and to more than 5.0% for Mexican oils. Sulfur is important because it forms disagreeable compounds with the hydrogen, nitrogen, and hydro-carbons in the oils. These compounds, some of them gaseous, are given off during the process of distillation. The most difficult odors to control occur when a refinery is operating with Mexican or other oils high in sulfur. Certain refineries in New England began operations with Mexican oil, and with no devices to prevent the escape of odors. The reaction by the public was instantaneous and violent.

Typical Refinery Practice

Although this paper is not descriptive of oil refining, and although the practice of this art varies greatly, it seems well to outline the general practice in order that the methods of odor control may be understood more readily.

Refineries may be classified in two general groups, namely, skimming or topping plants which confine their operations to the separation of gasoline and the lighter oils from the crude oil, and complete refineries which split the crude product into gasoline, naphtha, kerosene, gas oil, light and heavy lubricating oil, fuel oil, paraffin wax, pitch, coke, and other products, as the markets demand. There are many modifications of these two kinds of plant. For example, either may be operated in conjunction with a so-called high temperature distillation or cracking plant which, through heat and pressure, splits off hydro-carbons of lower boiling point from heavier oils, that the yield of the more profitable gasoline and lighter products may be increased. Then, again, it is unprofitable for certain refineries to carry the distillation until only coke remains in the stills, and such may stop distillation when the residue in the still is suitable for fuel, or, carried further, is a semi-solid pitch or petroleum asphalt.

Figs. 2 and 3 show the flow sheet for a complete refinery and the main features of a crude oil distillation plant, respectively. Although the kinds of distillate from the still are numerous, this paper concerns itself chiefly with the lighter products, some of which may escape from the refinery in gaseous form, and the heavier oils, pitch or coke, which, when hot, are likely to give off strong odors. Coke cooled with water is apt to emit an odor when the steam which arises from it carries away the odor of the coke.

During ordinary distillation, carbon accumulates on the shell of the still and the scale thus formed has to be removed by hand at frequent intervals.

The cleaning of stills, or tubes, is particularly frequent with the cracking process, in which high temperatures and pressures favor the deposition of carbon and make delays in cleaning dangerous.

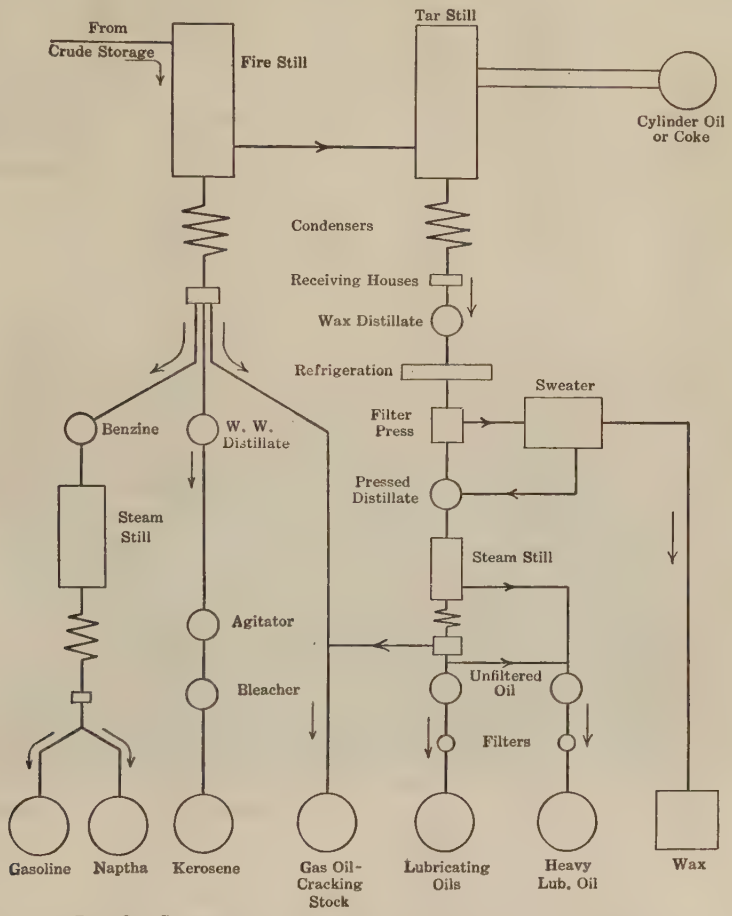

FIG. 2.—SCHEMATIC SEQUENCE OF OIL-REFINING PROCESSES.

Fuming sulfuric acid and lead oxide are used to treat gasoline and other lighter products to improve their odor. This is especially necessary if the crude oils contain sulfur and saturated hydro-carbons. This operation is usually conducted in tanks, operating either on the batch or the continuous system. The sulfuric acid carbonizes some of the asphaltic bodies and unsaturated hydro-carbons which settle to the bottom of the tank with the sulfuric acid, in which form the mixture is known as sludge acid. This mixture is washed with water and the sludge oil separated from the weak acid. Frequently, the acid is recovered by concentration and the process may be conducted so as to be extremely offensive. The sludge itself becomes acrid and offensive, especially in the vicinity of the refinery, but fortunately the odors are heavy, are soluble in water, and are not carried far away.

FIG. 3.

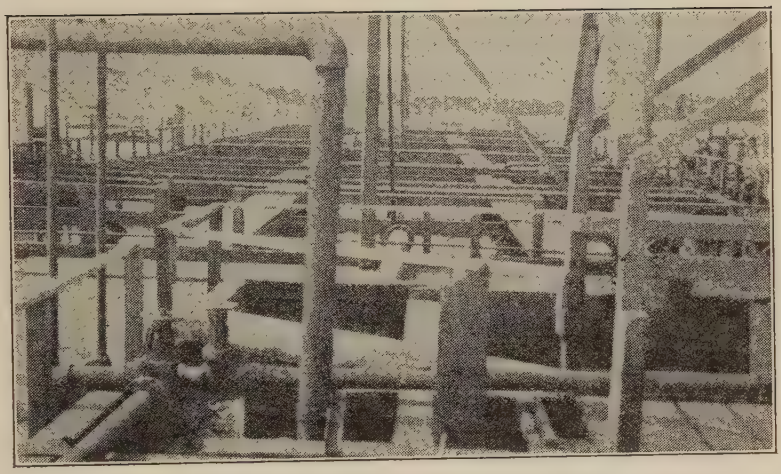

FIG. 4.—SKIMMING OR SEPARATOR TANK.

As will be seen from Figs. 2 and 3, nearly all the processes require water for cooling, and this, together with whatever oily waste may escape from the plant through leaky condenser coils, by accident or otherwise, is usually discharged from the refinery in a common drain, discharging in turn into a large subsiding basin (Fig. 4), in which ample time is given for the removal, by gravity, of the subsidable solids and the skimming off of waste oil.

The effluent from such a basin should not contain more than 20 parts of oil (ether soluble) per million. Frequently these basins, especially when the condenser waters are warm, give off objectionable odors. Especially is this true when there is accidental leakage of volatile products or when batches of distillate, improperly processed, are salvaged by discharge into the drain and by skimming from the subsiding basin.

Where lubricating oils are made, it is necessary to filter them through fuller's earth, diatomaceous earth, or similar material. It is sometimes necessary to filter gasoline, kerosene, and other products, also. After the filter material is exhausted or clogged, it is necessary to regenerate it by heating in a rotary kiln until the waxy accumulations are volatilized. If the dust and oily vapors from the kiln are discharged directly into the air, offensive odors may be carried for miles, apparently in the form of colloidal particles of oily dust.

The crude oil from ship, tank car, or pipe line is stored in large tanks, usually of steel, and covered. It is obvious that, during the process of filling, the gaseous products accumulated in the empty tank from a previous filling will be discharged into the atmosphere, the tanks inhaling air and exhaling petroleum vapors alternately. There is also evaporation, which is greater if uncovered tanks are used.

The boilers, stills, and cracking plants are oil or gas-fired and give off the products of combustion characteristic of oil-fired furnaces. These products possess the characteristic burned-fuel-oil odor so frequently noticeable in localities where fuel oil is burned, beneath the boilers of ships, locomotives, and stationary steam plants.

The main sources of odor may be listed as follows:

(1) The gases and vapors from crude oil.
(2) The volatile gases given off by petroleum when distilled.
(3) The vapor from heated oil, especially oil heated to a high temperature during the "cracking" process.
(4) The vapors and dust from kilns used to regenerate filter material.
(5) The heavy acid and acrid odors resulting from treating oil with sulfuric acid and other chemicals. This odor is especially strong when the oil and acid are agitated by compressed air in open tanks.
(6) The emanations from the surfaces of subsiding or separating basins and from the surface of water in gas-holders.
(7) The vapors given off from hot coke or pitch freshly drawn from the still.

(8) The vapors given off from stills when opened and steamed after a distillation has been completed.

(9) The stack gases from oil-fired furnaces; this is the most prevalent odor.

The substances included in these odors are petroleum and asphaltic hydrocarbons, hydrogen sulfide, carbon bisulfide, sulfur dioxide, sulfur trioxide, pyridin vapors, the oxides of carbon, and various volatile compounds of sulfur or sulfur and nitrogen, of which the offensively smelling mercaptan is an example.

That some of these odors may be present in the air in sufficient concentrations to affect the health was shown by the studies of Mr. S. DeM. Gage,* who reported that during 1921 at least ninety-six persons in the vicinity of Rhode Island refineries had been more or less seriously affected by them. The symptoms most frequently noted were nausea, headache, vomiting, sore throat, and insomnia, and it was the opinion of the majority of physicians consulted that asthma, respiratory diseases, and nervous diseases were unfavorably affected by petroleum and sulfur odors and also by the sulfur dioxide and trioxide gases.

Nature of the Odoriferous Matters

The matters which produce the odor may be divided into two classes, namely, true gases and vapors. The true gases diffuse rapidly and the intensity of the odor roughly varies inversely as the square of the distance. Not so the odor produced by vapors which, in the form of minute particles, "odorphores", impinge directly upon the olfactory organs and seem to lose their intensity very slowly with distance within the sector where their presence may be observed. The distances to which they may be observed seem to depend more upon the humidity and the character of the air currents which carry them than upon any other factors.

For example, the writer has observed the acrid odor from sludge acid when it was so strong that it was impossible to remain a whole minute in its presence. Yet this odor could not be observed ½ mile to the leeward of its point of origin. On the other hand, the sulfur compounds in the vapors given off from Mexican oil were at least one-fourth as intense 2 miles away as they were in the refinery yard where they were produced.

The odors from the kilns in which material used to filter the various distillates is ignited to regenerate it, also have the power of traveling great distances. This is probably due to the fact that the dust particles from the kiln become coated with a film of oil, and in this state become dispersed in the air, much as pollen and other dust particles are dispersed.

Character and Intensity of Odors

It is a fact of physiology that the nose detects two classes of odors: First, the true odors which are observed by organs located in the upper nasal passages behind the superior turbinated bones; and, second, the irritants which are observed by a separate set of nerve endings in the anterior part of the

* Report of Rhode Island State Board of Health on the Cause, Prevalence and Effect of Offensive Odors in Providence, Cranston, East Providence and Warwick during 1921.

nose. For example, perfumes are perceived by one set of nerves, whereas irritants like ammonia and pyridin, affect the other set. Certain substances like tobacco smoke, for example, are both odoriferous and irritating, and the odors given off by oil refineries are in either or both of the two classes.

Oily vapors, for example, volatilized vaseline, possess true odors which are not irritating, whereas sulfur trioxide is sometimes recognized by its irritating effect, before being detected by the olfactory organs. Certain volatile hydro-carbons are also highly odoriferous, but are not irritating unless present in high concentrations.

It is a peculiarity of the olfactory organ, by which the true odors are detected, that it tires rapidly and that ordinarily sniffing is required to carry odor to the portion of the lining membrane of the nose where in a small area (25 mm. square on each side) the special organs are located.

Names of Odors.—Various observers have given names to the various odors, and sometimes various names to the same odor observed about oil refineries. For convenience, the following adjectives have been used in the writer's practice:

Adjective.	Description of Odor.
Sweetish	The odor of gasoline and refined petroleum products.
Turnipy	The odor of well-diluted petroleum gases containing sulfur and nitrogen.
Onion or garlicy	The same odor in higher concentration.
Sulfide	The rotten-egg-like odor of hydrogen sulfide gas.
Sulfur trioxide	The characteristic odor of fuming sulfuric acid. In considerable dilutions this is detected by its effect upon the mucous membrane and without the accompaniment of any true odor.
Oily	The odor of volatilized petroleum distillate as from a fuel oil tank.
Burned oily	The characteristic odor from oil-fired furnaces.
Burned rubber	The burned oily odor in higher concentration.

Any of these odors may exist singly, or in combination, and the combinations may possess odors and irritants which are difficult to analyze.

Intensity of Odors.—The intensity of odor may be graded on a scale of 5, as follows:

Number.	Corresponding Adjective.
1	Very faint
2	Faint
3	Distinct
4	Decided
5	Strong

Detection of Odors.—Two methods of detection are usually practiced, namely, smelling and chemical analysis.

Smelling.—The nerve ends in the nose not only are delicate qualitative instruments, but when the results of their trained use are classified and the adjectives pertaining to quality are given numerical values, they do more

reliable work than any mechanical instrument; because, after all, the reaction of a complaining public depends upon nasal observations and not the qualitative results of chemical air analyses, which are of little practical meaning to them. Furthermore, an observer becomes expert with training and can detect and describe odors which baffle a lay observer. His observations are of especial value when a differentiation of sources of odor is required.

Gas Analyses.—Chemical gas analysis methods are more effective for the detection of the irritating sulfur gases, it being possible to measure concentrations which are about one-tenth of those which may be detected by the nose. For example, hydrogen sulfide may be smelled in concentrations of 100 parts in 1 000 000 000 parts of air, whereas the same gas may be detected in concentrations of 15 parts in 1 000 000 000 parts of air, by chemical analysis, using 100-liter portions for each determination.

The Nasal Method.—The first requisite for this method is an observer of keen perceptions, one who is quick to notice any change in atmospheric conditions and who can make judicial records of his observation.

The automobile is a great convenience for making observations, but care should be taken to select a machine which emits the minimum of oily odors, and when making observations, the observer should step out of the automobile so as to avoid any error due to observing the products in the exhaust of the motor in place of those present in the air at the point of observation.

While making record of nasal observations, together with those of wind and weather, a sheet, Table 10, has been used by the writer's firm. It will be noted that there are spaces for recording the velocities and the direction of the wind at various times of observation, the weather, and the time, place, kind, intensity, and probable source of any odors observed. Space is also provided for smoke observations for the reason that the burned oily odor from stacks connected with oil-fired furnaces, is more or less proportional to the density of the smoke emitted from them.

At Fall River, Mass., eight stacks were observed. Some of these were within the refinery yard, and others were connected with various mills within two miles of the refinery. Ringelmann's chart was used to record the percentage of black smoke in the emanations from the various stacks. The relative humidity was observed at one station only.

Having made the observations, the next step is to express them in diagrammatic form. For this purpose, reproductions of a map of the vicinity of the refinery about which observations are made, are useful, and Figs. 5 and 6 show the map-diagrams which were used at Fall River and at East Braintree, Mass., and vicinity, respectively.

The Fall River map-diagram (Fig. 5), which records the observations for 24 hours ending at 7 A. M. on July 25, 1922, shows a summary of the weather, wind, smoke observations, the intensities and kinds of odors, and the areas within which the odors were observed. It will also be noted that odors were observed as coming from three sources, one of which was the oil refinery and the others manufacturing plants where boilers were fired with oil. Compared with a large power house, an oil refinery is a small consumer of fuel oil, and

frequently odors detected in the vicinity of a refinery are properly chargeable to the furnaces of public service and manufacturing plants.

The diagram used at East Braintree, Mass. (Fig. 6) shows a little different method of recording results. The observations at this place benefited by the use of a recording weather-vane, which avoided many errors in observations of wind direction, especially those due to topographical features near the points of observation.

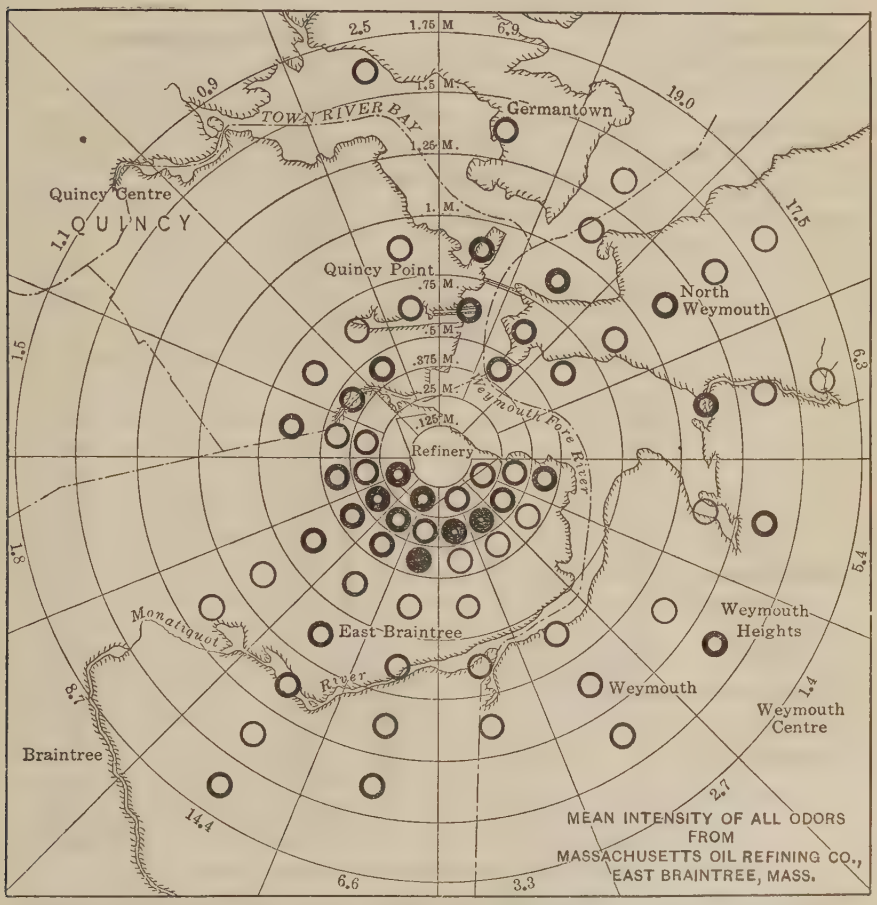

FIG. 6.

On the diagram referred to (Fig. 6), various data were recorded by the use of symbols, and the illustration is one showing the mean intensity of all odors in each sector of 22.5° and the relative mean intensities of these odors in the section of each annulus lying within the sector, the mean intensities in each sector being expressed by figures, and those in each section of an annulus by circles of varying heaviness.

Chemical Analysis of Air.—The modified Palmer machine (Fig. 7), which has been described previously by the writer* has been used quite successfully

* *Transactions*, Am. Soc. C. E., Vol. LXXXV (1922), p. 420.

for the estimation of the amount of sulfur gases contained in the air. This machine is operated by a small electric motor, and unfortunately requires the installation of numerous lighting sockets, preferably on the poles of the electric lighting system, in order to operate it over any considerable area of country surrounding the refinery under observation. The stations at Fall River and East Braintree were located at the points indicated on the map-diagrams (Figs. 5 and 6) by numbered rings.

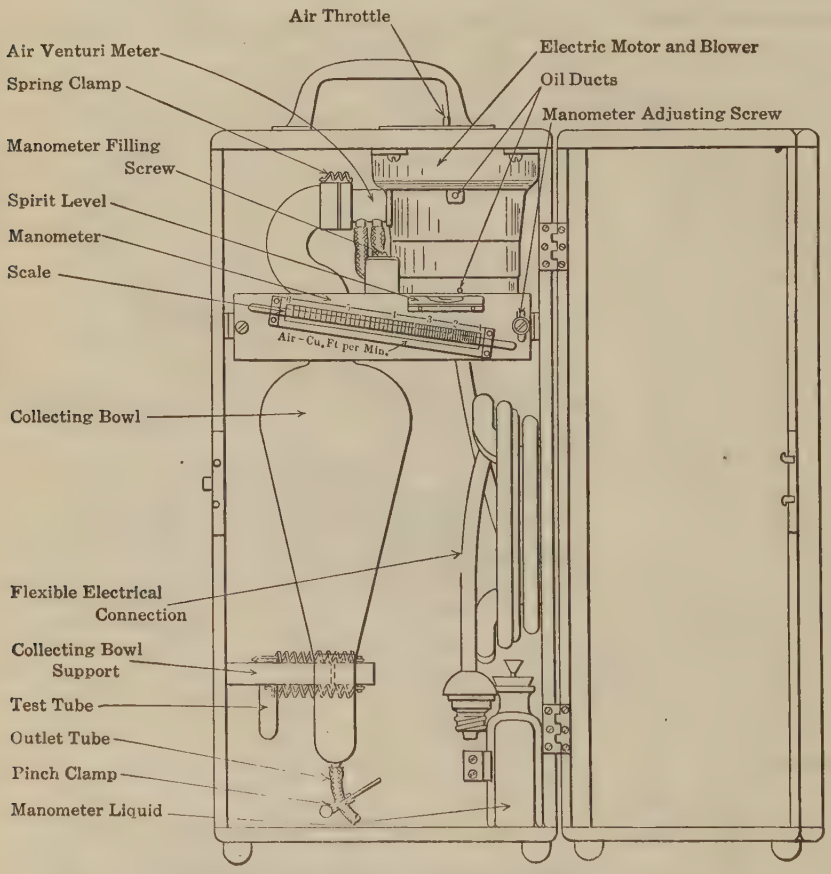

FIG. 7.—DUST SAMPLER, PALMER WATER SPRAY TYPE.

By means of the Palmer machine, 100 liters of air could be aspirated through nebulized caustic-soda solution and the sulfur gases absorbed determined by the usual chemical method. This method is similar to the one used by the copper companies in the West for the detection of sulfur dioxide in the gases emitted from smelters. Usually the concentrations of gas found in the air were very minute, although concentrations as high as 50 parts per 1 000 000 were observed in the vicinity of sludge acid tanks, but beyond a mile of the refinery conditions are unusual when 1.0 part of sulfur gas, computed as hydrogen sulfide, was found. Unfortunately, this method of absorption cannot distinguish between sulfur dioxide and hydrogen sulfide.

The presence of a faint burned-oily odor in the vicinity of a refinery, and extending some distance to the leeward, is to be expected, just as the same odor is observed to the leeward of any manufacturing plant using oil in the power house. It is desirable, however, that no other odor be present, and it is possible to conduct a refinery so that the presence of any other odor will be the result of accident only. How the control and elimination of these odors may be accomplished is described subsequently.

Control and Elimination of Odors

General Methods.—There are two general methods used to eliminate odors from petroleum gases and distillates. One method is to pass all the gases through a scrubber and absorb them in water which in turn is discharged into the nearest large body of water, usually through a skimming tank or separator. The objection to this method is that the water used to scrub the gases is as capable of liberating the gases under certain conditions as it is of absorbing them under others. Consequently, objectionable odors are frequently absorbed, only to be given off again later.

Petroleum distillates have been used to scrub the gases, in place of water, the aim being to re-distill the combination and recover a part of the volatile matter in the form of gasoline, thus increasing the gasoline production of the refinery. This method often fails because of the gaseous character of the compounds which refuse to remain absorbed in the finished product. Consequently the method only postpones the final disposition of the odoriferous compounds.

The best method yet devised for eliminating the gaseous petroleum compounds from the air, particularly those offensive ones containing sulfur and nitrogen, is to collect them by means of a vacuum system, and to burn them beneath a still or boiler. This method is not only practicable, but effects a considerable economy of fuel.

The danger in carrying out this process is one of forming explosive combinations of air and petroleum vapors. This can be guarded against, however, by placing Monel metal screens (Figs. 8, 9, and 10), at various convenient points in the collecting piping. These screens act upon the safety-lamp principle and prevent backfiring of the vapors.

Another requisite of the process is to provide for variations in the rate of gas emanation, for it is obvious that when a still is freshly charged, the rate of gas evolution from it is greater than later in the distillation process. On the other hand, the rate of burning gas beneath boilers is more nearly constant. Consequently, it is necessary to store the gas during the peaks in production for use during periods of low production. For this purpose, gas-holders similar to those used in illuminating gas-works are used. The gas-holders are connected with the gas mains, and maintain a practically constant pressure at the burners beneath the stills, furnaces, or boilers. A partial vacuum of a few inches of water is maintained throughout the system by exhausters similar to those used in illuminating gas practice. These exhausters must be of ample capacity to exhaust the gas regardless of the rate of production.

It is usual to provide two vacuum systems, one connected with the stills, from which gases rich in combustible material are collected, and another system connected with the tanks, the collections from which are comparatively weak in combustible gases. The collection system for the tanks is somewhat different from that for the stills in that some air is collected at all times.

Each tank is usually provided with a seal or trap (Figs. 11 and 12), having a water seal equivalent to a depth of water of about 1 in. Consequently, when the tanks are connected with the vacuum system, a slight partial vacuum is maintained at each tank where odors are likely to be produced. Exhausters on the gas main maintain the desired vacuum in the tanks. A higher negative pressure is maintained on the still gas lines.

With the whole refining process conducted under a partial vacuum, little or no petroleum gas can escape into the atmosphere unless its combustion beneath stills and boilers be incomplete. Figs. 13 and 14 show the types of burner used beneath the boilers of a refinery in Massachusetts.

Naturally different burners have to be provided for the combustible gases distilled from the petroleum than for the enriched air exhausted from the storage tanks. The first is utilized like any other gaseous fuel. The second is used as if it were a semi-inflammable air used to support and accelerate combustion. The difficulties of caring for either the petroleum gases or the enriched air are those connected with maintaining a proper temperature in the furnace. In the case of the enriched air, it is usually necessary to burn it in conjunction with fuel oil, and in both cases the construction of a suitable checker-work of brick to make sure that all the gases are raised to the point of ignition is necessary.

Occasionally stack gases will show evidences of having been imperfectly consumed in the furnace, and where oils high in sulfur are refined, may contain the objectionable nitrogen-sulfur compounds. The usual remedy in such cases is to raise the temperature of the furnace, although experiments made under the direction of the writer have shown that the introduction of a small amount of chlorine gas into the stack gases will so change their character that they will become unobjectionable. This process is the one so successfully applied by Professors Henderson and Haggard to garbage plants to overcome the disagreeable odors emanating therefrom.

Odors from Sludge Acid.—The disagreeable acrid odor given off by sludge acid is difficult to control. In some plants, the material is removed and covered with earth. This requires a large area, usually not available in connection with a refinery. The sludge is washed in water to recover the acid and the weak acid is concentrated by distillation in a closed system provided with devices for maintaining a partial vacuum by a method similar to that used in the petroleum stills. By the use of this apparatus, in which the weak acid may be agitated with superheated air, or heated in a retort, the emanation of disagreeable odors may be eliminated. Furthermore, the recovered acid may be re-used for refining oil.

Because the actual volumes of sludge acid discharged from a large plant are small, it is frequently advisable to ship acid from several refineries to a

central plant for the reclamation of the acid. This plant may be located where there is the minimal danger of nuisance.

The Discharge of Oil into Watercourses.—It is probable that the befouling of shore waters and bathing beaches by discharges of oil has given rise to as serious complaints as the discharge of odor into the air. It is beyond the province of this paper to discuss this nuisance except to state that the discharges which come or might come from an oil refinery are readily controlled by skimming off separating tanks, the effluent from which should not contain more than 20 parts per 1 000 000 of ether soluble oil, the discharge of which in so great dilution into any considerable body of water may be made with impunity. Usually the befouling of shore waters and beaches is from shipping and sources other than oil refineries.

Although the principle of odor-control by operation *in vacuo* is simple, its carrying out is a matter requiring care and involving large expense for construction, maintenance, and inspection. It is not enough to have a single connection with each still or condenser, but each high point must be connected with the general system through a separate pipe, each pipe provided with a shut-off valve for use in case of accident. (Figs. 15, 16, and 17.) Furthermore, the workmanship must be of the best to avoid gas leakage. In addition, frequent traps (Fig. 18) for the interception of liquids are necessary, and also devices for separating the intercepted petroleum products without discharge into the air. Fig. 16 shows the extensive piping required to exhaust the gases from a battery of stills.

Not only must the stills be vented, but the use of open tanks for chemical treatment of distillates must be avoided. Fig. 19 shows the method of covering tanks and exhausting the gases arising from a group of agitators.

The control of the odors emanating from the skimming basin is seldom attempted. Fortunately these odors are not usually strong except when accidental discharges of the lighter distillate happen to occur. Usually the odors are imperceptible beyond the refinery yard. The method of guarding against their spreading is to construct a high fence about the basin to minimize the movement of air currents.

Naturally the water in a gas-holder absorbs and gives off disagreeable odors. These may be largely controlled by renewing the water in the gas-holder and by preventing the circulation of the exposed surface water as much as possible. In some cases the addition of chemical absorbents has been practiced, but not generally.

Summary

Briefly, it may be stated that unless controlled, the odors emanating from an oil refinery may create a nuisance. These odors are due to various vapors and gases emitted during the process of refining, and the best method of controlling and eliminating them is to collect them at all possible points of discharge by means of vacuum-collecting systems, to store the gases so collected, and to discharge them into properly designed furnaces in which, with or without the aid of other fuel, they will be completely consumed.

Travelers have reported that in the "Black City" near Baku, in Russia, where there are 200 refineries which treat the whole of the petroleum of the district, the odor of petroleum is perceptible at a great distance and the town is always covered and surrounded with dense, black smoke. It is obvious that this condition ought not to exist in the vicinity of refineries which are near large centers of population in the United States, and they should be controlled by proper methods, even if their installation may cost 10% as much as the total cost of the refinery construction. It is fortunate, on the other hand, that the investment in a gas-collecting system is compensated in great part at least by the large saving in fuel due to the utilization of combustible gases for heating stills and boilers.

Air cleaning, like river and harbor cleaning, is a problem connected with the concentration of population and has become an art which all communities that wish to maintain a high degree of civilization, with health and happiness for all, must practice.

In conclusion, the writer wishes to thank the officers of the New England Oil Refining Company, and particularly Mr. D. T. Schulz, General Superintendent, for permission to publish certain information, and assistance in preparing the illustrations in this paper.

DISCUSSION

JOSEPH A. WARREN,* ESQ.—Except in England and the United States the system of law prevailing among all the civilized Caucasian races is what is known as the Civil Law. That law takes general abstract principles and applies them to each state of facts as it comes up. It makes for rigidity, and it makes for certainty.

The American system of jurisprudence, however, is known as the Common Law, and that takes a given state of facts as it happens and applies to the interpretation of such facts the custom and the general understanding during past and present times of the community in general. As can readily be seen, under the latter system the law is continually in a state of flux, and it is very difficult to say in advance what the Courts are going to do in regard to any given state of facts. A very striking example of that is had in this very law of nuisance.

As stated by Mr. Goldsmith, in the early cases the law looked at the injury to property almost exclusively. It was the damage to an individual's property that laid the foundation of all action, and that was true not only with respect to the law of nuisance, but generally. The old common law looked at the damage to property—damage to an individual suitor. With the change of the customs of the people, with the growing civic consciousness, there has been a gradual getting away from the emphasis formerly placed on property damage, and the Courts look more to the interests of the community at large than to those of the individual property owner; and if the individual property owner's rights interfere or injure the community at large, the Courts are very active in finding some way of serving the general interest even at the expense of the individual property owner.

The most striking example of that attitude in recent years is the upholding of the rent laws of New York by the Court of Appeals of that State and by the Supreme Court of the United States. Formerly, the emphasis was on the injury to property, but now most emphasis is placed on the health and interest of the public or of any considerable part of the public.

In the same category is the rule mentioned by Mr. Goldsmith that one cannot move into a nuisance. At common law, if a business existed, that might be a nuisance, and any individual who, after the establishment of that nuisance, moved into the zone of influence knowing it was there, had no remedy. Where emphasis was on the property right, this was only fair; but that law is almost extinct.

Where a nuisance exists, because a community has grown up around it, the law, not to protect any individual who has moved there knowingly, but to protect the community, will make available the remedies that exist in the case of nuisance.

There was a rather striking example of the way this law works in the Edgewater case, referred to by Mr. Goldsmith. It is true that New York State in 1916 started suit in the United States Supreme Court against certain

* New York, N. Y.

companies in the State of New Jersey; but it is not quite accurate to state that the settlement that has resulted came from the litigation. Consider the peculiar problem there. One of the finest residential sections of the great State of New York was directly opposite those factories. Some of the factories were there before the upper part of Riverside Drive had developed into a residential section. All these factories were engaged in a kind of business that gave forth fumes, odors, and smoke. They were in another State. Jurisdiction of them could not be obtained in the State of New York. They were large commercial enterprises—the Corn Products Company, the General Chemical Company, the Barrett Manufacturing Company, and others of almost equal magnitude.

Officials started dealing with the problem in 1908. Nothing very definite was accomplished until 1917, when the Legislature of the State of New York passed an Act (Chapter 292 of the Laws of 1917) that gave to the State Commissioner of Health power to investigate those alleged nuisances and, if he found nuisances that affected the life, health, and safety of the people of the State of New York, to file in the office of the Secretary of State a certificate to that effect. If within thirty days those nuisances were not abolished, the charters of those corporations in the State of New York, if they were New York corporations, or their certificates to do business in the State of New York, if they were foreign corporations, would be automatically revoked, and receivers appointed for their property. In other words, a sentence of capital punishment was imposed on those corporations for maintaining nuisances. It would have meant the destruction of certain of those great corporations.

The remarkable thing about that legislation is that no one raised the question of its constitutionality, drastic as it was. Under the direction of the then Commissioner of Health, Dr. Biggs, elaborate investigations were conducted in the first instance to ascertain the source of the particular trouble in the City of New York, and then remedies were sought and suggested. Over a period of two years the hearings went on, and a solution was gradually worked out, so that, now, with a few occasional and rare exceptions, that nuisance in the City of New York is practically abolished.

In this proceeding the so-called psychological effect of nuisances was given much consideration. Probably no one went further in holding what might affect the health of the people than did Dr. Biggs in that particular case. The matter was adjusted so that the Courts have never had occasion to pass on Dr. Biggs' ruling, but without doubt they would have sustained him, particularly on the evidence in that case. It was held unnecessary to prove, for instance, that a considerable number got sore throats, or got any particular disease; but if the odors, the fumes, so disturbed residents that they lost sleep and that their general health and vitality was lowered because of this disturbance, this alone was sufficient ground to exercise the health authority of the State.

This whole case well illustrates the serious propositions that will come before sanitary engineers as the law develops in the future. In the first place, before this bill was passed various remedies had existed for years. There was the remedy by abatement in the Courts; the remedy by injunction in the

Courts; action for damages in the Courts; and the machinery of the Health Department for the direct suppression of nuisance without resort to the Courts. It is thought that in the future the remedies will be modeled on the last method, that is, abatement of nuisances through the administrative powers of the State rather than through the judiciary.

The Edgewater case further illustrated the fact that, when the present remedies are not adequate, either the legislatures or the Courts are going to devise some method that will be adequate to control the situation; and the tendency in all cases nowadays is to assign the remedy to the health authorities. Now, health authorities are rather uncertain; some of them are rather extreme. One can imagine that a very serious situation would have arisen in the Edgewater case if Dr. Biggs had been an arbitrary and radical Health Commissioner who at once, without proper hearing and consideration, would have endeavored to solve the difficulty by applying the very drastic measures of that law.

It is well to remember this—when the legislature refers to a health authority the determination of a question of fact as to whether a certain business does constitute a nuisance injurious to the health of the people, the determination by that health official will hardly ever be overturned by the Courts.

This experience suggests, therefore, that when any considerable commercial enterprise is being considered, not only the immediate vicinity of the location of the plant should be carefully investigated, but the whole probable zone which might be affected by any of the processes that are proposed to be conducted.

Further, in view of the fact that a future development may make a nuisance out of what previously was not a nuisance, it seems that, in so far as is reasonably possible, an investigation should be made as to the probable development of the locality, because, once a plant is established and developed, a situation may easily arise where the whole plant would have to be torn down and moved to some other location, or where the State might have to do it.

Charles A. Holmquist,* Esq.—In presenting this paper Mr. Gage has rendered a valuable service to the Sanitary Engineering Profession, more particularly to the Engineering Divisions of State Departments of Health which are perhaps called upon to deal with problems of this kind more often than any other organization. As indicated by Mr. Gage, nuisances created by odors are among the most difficult problems with which health departments have to deal, owing largely to the intangible and elusive nature of the subject and to the lack of scientific or standard means of measuring quantitatively the magnitude of such nuisances. The detailed description of the procedure and methods used in the investigation conducted by Mr. Gage of the alleged nuisance created by certain oil refineries in the Providence Metropolitan District should be very helpful to those who may be called upon to carry on similar investigations. The development of the formulas to determine the magnitude and degree of a nuisance is a long step in the right direction. The value of such formulas, however, would be considerably increased if

* Director, Div. of Sanitation, State Dept. of Health, Albany, N. Y.

numerical values could be given to intensities of odors similar to those given to tastes and odors of water supplies that are now in general use by water analysts. The speaker realizes, of course, the difficulty of doing this. In the first place there is no such thing as a standard nose. No two persons would probably re-act in exactly the same way to the same odor due not only to the physiological but also to the psychological difference of individuals. In fact, an odor that is objectionable to one person may be unobjectionable and even pleasing to another. Furthermore, all so-called odors are not true odors and do not stimulate the same sets of nerves. True odors, such as artificial musk and oil of roses, affect the cells of the olfactory nerves in the nasal cavity, whereas sulfurous acid and similar substances have no true odor, but are irritants which affect the ends of the trigeminal nerves. Other so-called odors affect both sets of nerves.

In view of the rapid increase in the number of industrial developments in centers of population, the ever-increasing number of sewage, garbage, and waste disposal plants in this country which are likely to give rise to nuisances due to the emanation of objectionable odors and the growing demand for higher standards of sanitation, it is evident that this problem will have to be given more attention in the future than in the past and that this subject might well be worthy of study by a committee. A great many tests have already been made to determine the concentration of different chemicals and other substances that are detectable in given quantities of air, and their relative intensities, but additional studies would be necessary to give definite values to such odors.

Mr. Gage points out that he has dealt with the methods of determining the cause, scope, and effect of odor nuisances and has left the discussion of methods of odor elimination to others. Considering the large financial investments and the great number of persons that are usually involved, remedial phases of the problem in most cases will be very important. The speaker will endeavor to discuss these phases of the problem from the point of view of State health departments and will cite a few instances that have come under his personal observation where odor nuisances have been successfully abated. In fact, it has been the experience of the New York State Department of Health that there are relatively few odor nuisances that cannot be abated by changes in operation of the plant, or the treatment, utilization, and recovery of waste products. Very often the abatement of such nuisances results in increased financial returns and sometimes in more sanitary and healthful conditions in the works themselves.

It has been the consistent policy of the Department in dealing with odor nuisances to co-operate as far as possible with the industrial plants in abating such nuisances and to issue orders and start Court proceedings only as a last resort. This spirit of co-operation is usually appreciated by the manufacturers and meets with their hearty response. Recommendations for improvements have often been carried out with relatively little delay. The owners of many of the plants investigated have probably felt, and some have admitted, that it would be cheaper in the long run to make voluntarily the improvements or

changes suggested by the Department rather than to take the question to the Courts with the possibility that the improvements would ultimately have to be made at their direction. The following cases are some of the odor nuisances that have been abated through the efforts of the State Health Department without the necessity of issuing orders or bringing action in the Courts.

Carbon Disulfide Works.—These works were situated in a narrow valley extending in a generally northerly and southerly direction. Complaints were received from residents of the valley that whenever the wind was from the direction of the chemical works very objectionable and stifling odors, fumes, or gases, were noted and that the fumes discolored paint on houses more than a mile from the works. From the investigation, it was found that the trouble was caused almost entirely by the liberation of hydrogen sulfide (H_2S) in the process of manufacture of carbon disulfide and that houses in exposed areas within 1½ miles of the works were discolored, especially those painted with lead paints. The carbon disulfide (CS_2) was made in the usual manner by passing sulfur vapors through charcoal heated to a cherry red in iron retorts. The uncombined sulfur vapors were conveyed to iron vessels in which these vapors were condensed and the sulfur was recovered. Some sulfur dioxide also escaped when the retorts were cleaned, but this gas did not appear to be an appreciable factor in the creation of the nuisance which was caused almost entirely by the liberation of hydrogen sulfide.

When the plant was first visited an attempt was made to eliminate this gas by passing it through a tank into which lime-water was pumped. Although some of the hydrogen sulfide was probably eliminated by absorption by the water and by reaction with the lime in the production of calcium hydro-sulfite ($Ca\ H_2\ O_2 + 2H_2\ S = Ca\ H_2\ S_2 + 2H_2O$), this method was not effective in abating the nuisance and was abandoned. Another attempt was made to eliminate the hydrogen sulfide by passing it through a wooden tower packed with lime and iron oxide, but the tower was found to be too small and the heat of reaction developed was sufficiently high to set the tower on fire. Finally, the nuisance was abated by passing the hydrogen sulfide through a Claus kiln consisting of two condensing chambers and an exit tower operated in series. The reaction chamber contained a layer of iron oxide through which the hydrogen sulfide mixed with a definite quantity of air, was passed after the oxide had first been heated to a dull red. This caused the reaction, $H_2S + O = H_2O + S$, to take place. The sulfur vapors were condensed in the second chamber of the kiln as liquid sulfur and in the third chamber as flower of sulfur. The water passed off through the exit of the third chamber in the form of steam. Some sulfur dioxide was carried over with it, but not in sufficient quantities to give rise to a nuisance. This installation resulted not only in the abatement of the nuisance, but also in the recovery of considerable sulfur which had formerly gone to waste.

Acetic Acid Plant.—Acetic acid was manufactured at this plant by distilling grey acetated lime with sulfuric acid. A pungent acetic acid odor sufficiently strong to cause a very uncomfortable irritating sensation in the nose and throat was found in the building in which the acid was made, and this odor was carried a considerable distance from the plant. A similar pungent

pyroligneous odor resembling acetic acid was also given off from the residue from the acetic acid stills and this odor seemed to carry very much farther than the acetic acid odor. When this plant was first inspected it was customary for the company to dump the residue from the stills on the floor of the still house, shovel the residue into dump carts, and haul it to a dump on the water-front where it would be left until a barge load or two had accumulated. This dump seemed to be the principal source of the odors.

The nuisance was abated by collecting and scrubbing the air in the building in which the acetic acid stills were located, by cleaning up the water-front, and by installing mechanical conveyors by which the residue from the stills was conveyed through covered chutes to covered gondola cars on a railroad siding outside the plant. The cars were removed as soon as they were filled. The scrubber through which the air from the building was passed consisted of a wooden tub about 10 ft. in diameter and 10 ft. high, filled with coke. Numerous sprays of water played continually on the surface of the coke, and the exit from the scrubber was connected to the stack of the power-house plant which was about 200 ft. high. Although no waste products were recovered, there was an appreciable saving in the cost of handling the residue by the mechanical conveyor.

Sulfuric Acid Plant.—In one plant of this kind against which complaint was made, the sulfuric acid was manufactured from pyrites by the contact process. Objectionable conditions were created by the escape of sulfur dioxide and a reddish dust from the burned pyrites which was stored on a dump outside the plant. Sulfur dioxide was found to be escaping from the exits of the absorbing towers and was so strong as to be almost unbearable within a few hundred feet of the plant when in line with the wind from the exits. The nuisance from this source was abated by utilizing the waste sulfur dioxide in the manufacture of sodium bi-sulfite. The exits through which the uncombined sulfur dioxide from the sulfuric acid plant formerly discharged into the atmosphere were closed, and the gas was conveyed to an adjoining building where it was passed through absorption towers through which a concentrated solution of sodium carbonate was circulated which resulted in the production of sodium bi-sulfite. About 80% of the sulfur dioxide was absorbed in these towers and a large part of the remainder was removed by scrubbing the exit gases from the bi-sulfite plant with water. The dust nuisance from the pyrites dump was eliminated by spraying the dump with water. Crude sulfur was later substituted for the pyrites in the process of making sulfuric acid.

At another plant where sulfuric acid was made by the chamber process, the acid was concentrated in platinum stills. The gases and acid escaping from the stills carried for a considerable distance and gave rise to a serious nuisance. These conditions were abated by changing the method of concentration and by installing a Cottrell machine for the condensation of the acid fumes.

Linseed Oil Works.—Characteristic odors given off from the process of making linseed oil although very pronounced near the works did not seem to carry any considerable distance from them. Very pungent odors, however, were given off from the process of boiling or aging the oil. This was done in covered steam-jacketed kettles in which the oil was heated to a temperature of

about 350° Fahr. for several hours while air was blown through the oil. When the oil works were first visited the oil vapors from the boiling kettles were conveyed to the breaching of the boiler plant. Owing, however, to the relatively low temperature at this point, and probably also to deficiency in oxygen, the oil vapors were not consumed but were simply scorched. Although the resulting odors could not be detected on the premises, they were very objectionable at a distance of a mile or more from the works. This nuisance was abated by connecting the vent pipe from the kettles with the firebox of one of the boilers. This seemed to produce complete combustion and eliminate the nuisance.

Coal-Tar Products Plant.—At a plant where coal-tar products were manufactured, large volumes of yellowish pungent oil vapors were given off when the stills were blown into the coolers. This nuisance was abated simply by closing the manholes on the coolers and installing vents by which the vapors were conveyed to coil condensers.

Starch and Corn Products Plant.—In this plant the corn was cleaned and then soaked or steeped with water containing sulfurous acid for the purpose of softening the kernels. After steeping, the corn was passed through cracker mills where it was partly crushed and the germ removed from the body of the kernel. The germ was separated from the remainder of the corn by gravity in shallow tanks filled with water and was dried in rotary driers, and ground, heated, and pressed to produce corn oil. The corn from which the germ had been removed was then ground in burhstone mills, and the mixture was washed and passed through fine mesh screens and silt reels a number of times in order to separate the starch from the gluten and other fibrous matters. The gluten and fibrous matters were passed through mechanical squeezers to remove the water, after which they were dried in rotary steam-heated driers to form gluten feed. The starch was settled out in long inclined troughs and then dried. Glucose was made by boiling starch paste with mineral acid, neutralizing the acid and evaporating the liquid.

A number of gases and odors were given off from the process of manufacture, including sulfur dioxide and sulfurous acid from the sulfur burners and the sulfurous acid plant and from the screen and reel rooms. A peculiar odor was also given off when the contents of the glucose retorts were blown into the coolers. The odor that seemed to cause the most trouble, however, was that discharged from the rotary driers where the gluten feed and the germ were dried. There were twenty-two of these driers which were vented into eleven large wooden stacks. Vapors approximating 40 000 cu. ft. per min. were discharged from these stacks. The odor of these vapors although difficult to describe resembled a combination of acid and organic matter not much unlike the smell of sour bread. These odors carried for a considerable distance and seemed to be nearly as intense a mile or two from the works as they were at the source. Considerable chaff was also discharged from the drier stacks with the vapors. A large part of this chaff was deposited on the adjoining buildings and premises, and some of it was carried long distances by the wind.

It was first thought that these odors could be eliminated by collecting them and passing them through a large water scrubber. Owing to the structural difficulties involved and the very large-sized scrubber necessary to care for the

vapors, tests were carried on with a new type of scrubber. This consisted of two concentric cylinders connected by a spiral plate arranged so that the vapors would take a spiral course in traveling from the inlet to the outlet while water was sprayed into the space between the two cylinders in such a way as to keep the surface against which the vapors came in contact wet. The vapors were forced through the scrubber by a fan at a velocity of about 5 000 ft. per min. While these tests were being made, an incident occurred which indicated very clearly that scrubbing the vapors by water alone would not eliminate the nuisance. One day while observations were being made at a point about a mile from the starch works, a very severe rain storm occurred. In order to determine the effect of the rain on the odors, the observer continued his observations in the rain for about 30 min., and it was found that, although the odors passed through a natural mammoth scrubber about a mile in length, they were not appreciably diminished in intensity.

An attempt was then made to deodorize the vapors by applying different volumes of chlorine gas to the base of the drier stack but, although sufficient chlorine was applied to be distinctly noticeable a considerable distance from the plant, the odor was not reduced to any appreciable extent. This was probably due in part to the inefficient mixing of the chlorine gas with the vapors and the short time of contact, but largely to the inability of the chlorine to deodorize or oxidize the particles of chaff carried out with the vapors. Tests were then made with the application of chlorine gas in connection with the experimental scrubber. Chlorine was applied first to the inlet and then at the outlet of the scrubber. Although the application of the chlorine gas to the inlet of the scrubber seemed to have no marked effect on the odors, its application near the outlet of the scrubber, but ahead of the fan, seemed largely to eliminate the odors, especially when sufficient water was used practically to condense the vapors and remove the chaff.

The company found, however, that the scrubbing and chlorination of the large volume of vapors given off from the exits of the driers would involve a considerable expenditure and would be costly to maintain and, therefore, abandoned that project. The vapors were finally collected and after passing them through scrubbers of the type experimented with, in order to remove the chaff which would otherwise have collected in the conduit, were conveyed to the forced-draft conduit of the power plant where they were mixed with about 200 000 cu. ft. of air per min., and burned. The burning of these vapors under the fireboxes of the boilers and the installation of a condenser on the exits of the glucose blow-tubes seemed to abate the nuisance effectively. Although no by-products were recovered as the result of the abatement of this nuisance, the sanitary conditions around the plant were improved appreciably, and it is no longer necessary to employ men to clean up the chaff which formerly settled on the roofs of adjacent buildings.

Many other cases could be mentioned but a sufficient number have been cited to indicate, in general, the nature of the problems involved in abating odor nuisances. Some of the problems are very simple; others are more complicated and difficult, but most of them can be solved by the intelligent application of chemistry, engineering, and common sense.

GEORGE H. SHAW,* M. AM. SOC. C. E.—As Chief of the Division of Housing and Sanitation in the Department of Public Health of Philadelphia, Pa., the speaker has encountered conditions similar to those described by Mr. Gage and Mr. Holmquist.

Philadelphia, with 2 000 000 inhabitants, is one of the largest manufacturing cities in the United States. In many places, manufacturing plants are located in close conjunction with residences; probably the conditions in this respect are as bad as those in any city in the country.

One of the serious nuisances is the manufacture of red oxide paint. In one large plant sulfurous acid is driven off and discharged from a tall stack spreading the fumes over the neighborhood. Everything possible was done to get the management to control this nuisance without success. It was finally necessary to take the case to Court and secure action requiring the manufacturers to abate this nuisance, which they did by discontinuing the "roasting" of the raw material in Philadelphia and transferring that operation to another city.

Another troublesome type of plant is that used for rendering. In one case it was necessary to institute criminal proceedings. Realizing that the law was sufficient to compel it to correct this condition, the company came to terms and spent a considerable sum of money installing control apparatus to abate the nuisance. Since then there has been no trouble.

Packing-house supply companies now sell rendering apparatus so constructed that the odors do not escape into the atmosphere. The apparatus is air-tight, and has an outlet to the sewer; so there is no further trouble with the cooking odors from open jacketed kettles. Many improvements in the handling of material have also been developed by packing-house engineers.

Another nuisance-producing industry that has given a great deal of trouble in Philadelphia is the oil refinery. In one large refining plant, sulfuric acid is used, which causes a nuisance when it is being recovered by distillation. To correct this condition a Cottrell electric precipitator was installed and has given satisfactory results.

In Philadelphia, there is a nuisance that Mr. Holmquist did not mention, that is, one due to the manufacture of electric storage batteries. Even workmen living close to such plants, who liked to sit on their porches in the evening and enjoy the fresh air, could not do so because of the presence of irritating acid fumes given off from the "forming room", where battery plates are manufactured or "formed" by electrolytic action. The co-operation of the company was secured and satisfactory control apparatus was developed. The air from the "forming rooms" is forced by fans through a condensing chamber filled with staggered fluted glass plates. The air, as it is drawn from the "forming room", goes through a tortuous passage, depositing the acid on the glass plates whence it trickles down the fluted surface and is collected at the bottom. A considerable quantity of acid is thus recovered.

It is believed that nuisances of the types mentioned have an indirect if not a direct effect on health and that their regulation properly comes within the

* Philadelphia, Pa.

"police power of a community." Experience has shown that they can be corrected and that rarely is it necessary to take drastic Court action. Helpful co-operation with the offending plant usually brings the desired result.

L. L. Tribus,* M. Am. Soc. C. E.—Mr. Gage has brought out one of the important features in considering odors, namely, the psychological effect—the effect that may be positively injurious and constitute actual legal nuisance. This was discussed somewhat in the speaker's paper entitled "Odors and Their Travel Habits."†

There is a peculiar difference in the effect of odors on different individuals, their personal equation. An odor might well be profoundly disturbing to the whole nervous system of some strong man, and, at the same time, be fully tolerated by some otherwise weak woman.

Another condition might be considered. How long does an odor affect an individual? Does the effect continue after the actual atoms have become dissipated, and memory reproduces the condition? The speaker thinks that it does, that even nausea can be reproduced long after the original smelling of the odor, if the first experience had caused such a condition.

John V. Lewis,‡ Esq.—Mr. Greeley brings out two points of prime importance which must be apparent to every sanitary engineer who has been concerned with the problem of refuse disposal at some time or other in his career.

The first point is the need for a collective technical effort and thorough engineering study of this ever-perplexing and acute problem which almost every growing municipality now faces. With due respect to those who have "blazed the trail", it is to be regretted that the same combined effort has not been accorded the disposal of rubbish, garbage, or mixed refuse, as has been given to sewage disposal. Had that been done, it is safe to say that the status of refuse disposal in its entirety would be quite another story.

The second point—and indirectly it is really a part of the first one—is that it should be understood that the problem, particularly as regards the control of odors, is one of engineering in its broader sense, namely, the education of the public and the injection of economics, just as much as the pure and applied sciences involved.

As mention has been made by Mr. Greeley of the Rochester, N. Y., plant as one of the most approved design and free from complaint as to obnoxious odors, some additional information may be of interest. From 1907 to 1921, the garbage of the city was reduced in a so-called modified Arnold plant. It was first cooked in large vertical steel digesters, and the resulting mass was then passed through hydraulic presses for the recovery of the grease. Drying and subsequent percolation were not used. The pressed tankage was sold for fertilizer.

The speaker is informed that the odors emitted from the plant, situated as it was in a commercial and industrial district about ¾ mile from the business center of the city, were the cause of numerous complaints during the period

* Cons. Engr. (Tribus & Massa), New York, N. Y.

† *Transactions*, Am. Soc. C. E., Vol. LXXXV (1922), p. 378.

‡ San. Engr., in Chg. of Refuse Disposal, Dept. of Public Works, Rochester, N. Y.

of operation. Most sanitary engineers are quite familiar with the difficulties which beset any one who advocates a new location for a garbage or mixed refuse disposal works, once it has been previously established. Thus, in constructing the new Rochester Reduction Plant, which began operation in 1921, the so-called straight Cobwell system was adopted as that which would best eliminate the cause of previous complaints and enable the existing site to be utilized. This site, which is at the geographical center of the city, greatly influences the haulage and several other important questions. The speaker believes that the success of this new plant and the failure of a similar one on Staten Island, New York, was essentially a question of geography and economics and not a lack of understanding of the technical side of the problem itself. The City of Rochester has the most up-to-date and sanitary garbage plant of its size in the country to-day, free from objectionable odors which may be the source of formal complaint. There is a constant endeavor to exercise technical control of the process used; to reduce still further the slight odors which do exist; and to place the collection system and the plant on an economic business basis. Such an attitude and effort were intended by those responsible for the inception of the new system.

As Mr. Greeley has pointed out, the control and possible elimination of odors from garbage disposal works must begin at the garbage pail itself, continue through the collection and haulage system, and end finally in the disposal works proper. If either of the modern sanitary methods of disposal called incineration and reduction are used, every effort exerted to collect the raw material in its fresh state and with the least water content means better control of odors and a reduction in the operating costs, both as regards haulage and the method of final disposal.

When through proper education of the public and diligent co-operative engineering effort, the collection and disposal of mixed refuse or garbage can be said to approach present-day methods for the collection and treatment of sewage, the problem will be nearer to a satisfactory solution.

I. S. Osborn,* M. Am. Soc. C. E.—In his paper on the elimination of odors from garbage disposal plants, Mr. Greeley brings out the fact that each stage in the treatment has a bearing on the subject as a whole. The house treatment, methods of collection, types of equipment, and methods of disposal are so interrelated as to require consideration of each.

If the most desirable solution from a sanitary standpoint is expected all phases of the problem must be considered. Mr. Greeley has indicated that the location of disposal plants in some cases should be determined by the type selected, and that the choice of a plant emitting odors requires an isolated site, whereas one free from odors may be nearer the center of production. Too little attention is given to the selection of the type of plant which can be erected in a central location when other factors enter and appear to dominate or control, such as length of haul, or cost of delivery of the refuse, and possibly ownership of the site where the right to operate has been established.

* Vice-Pres., The C. O Bartlett & Snow Co., Cleveland, Ohio.

Two cases of this kind have come to the speaker's attention. In one case, the accepted location increased the cost of haul by $30 000 per year over that of another available site, although the site selected had no advantages in its surroundings over the one rejected. In the other case, a site outside the city limits was selected and by so doing the hauling costs were increased approximately $50 000 annually over what would have obtained if another available site had been chosen. In each case the type of plant adopted was such that it could be operated in many locations without producing odors and without giving rise to complaint.

In many cities, the type of disposal plant is selected before a site has been chosen on which the plant can be located. However, the plant at Rochester, N. Y., mentioned by Mr. Greeley, was selected by a method directly opposite. The city owned the site and selected the type of plant to meet its surroundings. No other reduction plant is so well situated from the standpoint of cost of delivery of the garbage to the plant.

Mr. Greeley's statement with reference to the location of a reduction plant in isolated places in order to lessen the necessity for odor control is hardly supported by the facts. There is not a reduction plant disposing of garbage in an isolated location, and causing odors, to which those in the community where it is located do not object. There are, no doubt, fewer complaints due to the smaller number of people affected. In some cases the few tolerate the nuisance rather than assume the burden incident to a protest.

The establishment of districts under a zoning law, where odor-producing industries may be located, is done to protect property and industry. If plants, such as packing houses, rendering plants, and garbage disposal plants, are permitted, it is done to protect the industry as well as the public and not to legalize a nuisance from plants producing odors which may be eliminated.

With the Court rulings which have been made there is a question whether, even in an isolated location, the operation of a plant giving off odors will be permitted unless it is conducted in a manner to create as little nuisance as possible.

In discussing incinerators, Mr. Greeley states that "ample combustion and dust-settling chambers" should be provided, and that "satisfactory incineration over a number of years calls for durable construction with properly designed furnace structures to stand the relatively hard service."

Some of the fundamental features that should be incorporated in furnace design to give satisfactory service are, as follows.

Temperature.—The furnace should be designed so that a uniform temperature can be maintained when burning material with low heat value and high percentage of moisture, with assurance of temperature at all times sufficient to obtain complete combustion or oxidation without part of the gases passing off by distillation.

Fuel.—The design should be such that material containing a small quantity of combustible matter and a high percentage of moisture will burn without using additional fuel. This can be accomplished only by utilizing at maximum efficiency the heat developed in its operation.

Maintenance.—The cost of the maintenance of furnaces will depend on their design and the incorporation of features calculated to give proper protection under severe service. The design should permit of performing maintenance work without disturbing other parts of the furnace not in need of such work.

Thermal Efficiency.—The design should be such that the thermal efficiency will be high, using materials and construction that will insure only a small loss from radiation, with temperature developed to a maximum.

Draft.—The design should insure that all parts of the furnace can be balanced as to draft, including the furnace chamber, combustion chamber, flues, and chimney.

Simplicity.—A furnace for burning refuse adapted to the service for which it is intended, as well as the class of labor to be employed, and the material to be burned, should be simple in design.

Combustion.—Furnaces to insure proper combustion, should have:

(*a*) Ample space for combustion and the burning of material carrying a large quantity of hydro-carbon.
(*b*) Maintenance of steady high temperature in the fuel bed and in different parts of the furnace chamber.
(*c*) An adequate air supply, thoroughly distributed at the point where combustion takes place.
(*d*) Charging of the furnace and the manipulation of the fire without opening the fire doors or charging doors.
(*e*) The maintenance of a fuel bed on the grate whereby a variable quality of material will not influence the combustion or cause fluctuation in temperature.
(*f*) A high rate of combustion for maintenance of temperature and satisfactory operation.

Pre-Heating Forced Draft.—The pre-heating of forced draft air aids in combustion by supplying heat, thus permitting the burning of a lower grade of material; and, due to the expansion of the air in pre-heating, it permits of better distribution and, at the same time, reduces the excess air that would be required if it were not heated.

Structure.—To withstand the continued heating and cooling of the furnace, as well as to take care of the stresses developed under high temperature, the furnace should be designed as a structural unit with all the stresses that are developed in it taken up by the structural parts, the brick housing being installed for refractory and insulating purposes.

Mr. Greeley presents a table (Table 5) of analysis of organic garbage with the estimated quantity of coal that would be required to supply fuel and maintain a temperature of 1 240° Fahr. At this temperature, all gases or combustible materials will oxidize and be destroyed without producing odor.

A furnace, however, operating under variable conditions, such as charging and cleaning, will not hold a uniform temperature. The usual practice in high temperature furnaces is to maintain a temperature higher than is ordinarily required in the combustion chamber so as to insure that the minimum temperature will be sufficiently high to guarantee complete combustion.

The burning of mixed refuse in incinerators will insure better results than the burning of wet organic waste, which requires a large quantity of additional

fuel. It should never be necessary for any city to burn only organic wastes (kitchen garbage).

With a mixed collection of rubbish and garbage disposed of by incineration, in furnaces which consume the mixture at high temperature, the odors, with proper treatment in collection, storage, or combustion, will be prevented.

Investigation of plants burning organic waste (kitchen garbage) and using large quantities of additional fuel will show that there is a tendency to economize on fuel at the expense of operating with odors due to incomplete combustion.

Reverting to the question of odors, there are certain fundamental considerations which should govern the design and operation of disposal plants, varying, of course, with the system selected.

The adoption of preventive methods will prove more satisfactory than the elimination of odors after they are produced. Such preventive methods are applicable to all kinds of garbage disposal, including feeding, dumping, burial, reduction, and incineration.

Mr. Greeley's statement that relatively little progress has been made in the development of methods for odor elimination is hardly borne out by the facts, if a study is made of the beneficial results which have been obtained. The results obtained and the development made should not be confused with the failures resulting from neglect to apply existing knowledge.

The greatest criticism of present practice is that engineers are not using the experience gained, but continue to follow obsolete methods. When the best known practice in design and operation of disposal plants irrespective of the type or method is applied, more satisfactory results will be secured and continued improvement will follow. Study will show that to dispose of garbage satisfactorily and in a sanitary manner, without offensive odors, the cost will be higher either in capital investment or operation, or both. This will apply to practically all methods of disposal.

Probably no other branch of municipal service has received so little real study to determine the results that can be obtained or the improvements that can be made. Many officials and engineers look on the problem as one to be side-stepped. In many instances the question is considered from what is assumed to be an economic standpoint, the selection of type of plant or method of disposal being based on the least possible capital outlay.

The sanitary engineering problems of municipalities have received study and improvement and gradual development have been made. When municipal officials and the Engineering Profession realize that the disposal of garbage in a sanitary manner is a function requiring study, and look on it with the same interest as they do on other municipal problems, improvement will be made. When the problem is considered from this viewpoint plants will be constructed and operated which are free from odor, and there will be improvements in design and operation from every standpoint.

Morris M. Cohn,* Esq.—The subject of the control of odors from sewage plants has always been one of vital interest to those associated with the disposal of the city sewage at Schenectady, N. Y. The treatment plant was

* Supt., Bureau of Sewage Disposal, Schenectady, N. Y.

turned over to the City and operation commenced in January, 1915. The odors arising from the untuned Imhoff tanks, trickling filters, and sludge beds caused several property owners in the vicinity of the works to bring suit against the City to restrain it from operating the plant. The complaint stated an action for an injunction with fee damages, in view of the "exceedingly disagreeable, obnoxious and unhealthy odors" wafted to the plaintiffs' lands, about 1 500 ft. from the plant site. The action was begun in July and tried in November, 1915. Many lurid descriptions of the horrible odors in question were presented by witnesses. One day during the trial the Court and attorneys visited the plant. The cold weather had caused a cessation of intense bacterial activities in the treatment units and no odors of any kind were detected at a distance of less than 100 ft. It was the opinion of the Court that it had not been shown that the City could not run the plant without nuisance in the future and an injunction was denied. Fee damages were not allowed as no injury to health or no expense had resulted from the period of nuisance. The Court, however, advised the plaintiff that another action would be entertained if a repetition of such nuisance occurred.

Thus, at the beginning of 1916, a grave problem confronted the City. On the ability of the operators to control the odors from the plant depended the life of an installation that had cost approximately $500 000. The success that has resulted from the intelligent and careful manipulation of the treatment units is best shown by the fact that no formal complaint has been lodged against the plant in the past nine years, although most of those who signed affidavits of avowed nuisance in 1915 are still residents of the district in which the plant is located. It will be interesting to note the conditions existing at the treatment works at the present time.

Crude Sewage.—The crude sewage that comes to the plant is representative of the average American weak domestic flow. It seldom contains more than 200 parts per million of suspended solids and the daily variation is slight. The sewage is fresh and always contains an appreciable quantity of dissolved oxygen. About 65% of the total flow treated is pumped at a station about 2 miles from the works and little, if any, unbroken feces reach the plant. The odor of the liquid is soapy and has no tendency to become disagreeable unless the flow in the trunk sewer is greatly diminished and the sewage takes on stale characteristics on its way through the conduit. Whenever the pumping station is not in full operation, the flow in the trunk sewer is maintained by cutting in a 24-in. line that ordinarily is by-passed to the river because of the inability of the plant to handle the entire sewage flow of the city.

Bar Rack.—The crude sewage is passed through a stationary coarse bar rack that removes on an average ½ cu. yd. of wet trash per day. These screenings consist of rags, waste, paper, and all forms of garbage, which are disposed of on a dump. It has been found that this deposit gives off a distinct odor of garbage in the spring when it begins to dry out, but when dried it smells only like humus. In order to overcome this putrefactive tendency, the deposit is spread, covered with dry hypochlorite of lime, and then composted with sand. The odor is thus controlled with great certainty.

Present plans call for spreading the trash in the field and periodically plowing the accumulation under.

Imhoff Tanks.—After passing the bar rack, the sewage flows through the influent piping and submerged shear gates into the sedimentation compartments of the Imhoff tanks. This method of influx now replaces the old open influent channels that exposed the sewage to the air and retarded the velocity of flow to such an extent as to produce a deposition of solids in the invert. Overcoming this possible source of odor has done much to improve the sanitary conditions about the works.

The surface of the tanks are kept clean at all times by skimming, and the solids thus removed are thrown into the gas vents and hosed. The water supply of Schenectady contains about 160 parts per million of hardness and produces great quantities of insoluble soap curd that float on the tank surfaces. This grease has a tendency to give off a rancid fat odor under summer heat and great care is taken to skim off this material and to hose the sedimentation compartments frequently. All concrete surfaces and channels are kept clean by hosing.

Fine screens of $\frac{1}{4}$-in. mesh placed at the effluent weirs of the tanks and auxiliary screens of $\frac{1}{2}$-in. mesh placed in the effluent channels leading to the dosing tanks prevent much solid matter from passing over to the filter stone and there producing odors.

The old influent channels now act as effluent carriers, and, therefore, one set of such channels is always out of service and filled with stagnant sewage. Metal flash-boards are placed at the dead weirs to keep floating solids from being blown into this quiescent liquor and there putrefying. In summer, there is a tendency for this stagnant sewage to become stale, and, therefore, flow is reversed once each week to avoid any chance for septization and the consequent escape of sulfide gases.

As is generally known all Schenectady sludge rises into the gas vents to produce a scum blanket that is more than 6 ft. thick in the spring. This scum is driven down with a $1\frac{1}{4}$-in. stream of water during the entire sludge-drawing period. The first hosing of the year produces a sour odor that may be caused by the fermentation of the great quantities of mash that clog the gas vents, but subsequent hosings result in only a slight tarry odor about the tanks. A phenol-derivative disinfectant was used with some success to offset the slight odors produced, but the cost proved prohibitive. The gas vents have been raised by means of wooden chimneys, 1 ft. high, closed with hinged covers. This retards the foaming over of the scum into the sedimentation compartments and prevents the dissemination of scum odors into the air.

Dosing Tanks.—On passing into the dosing tanks, the tank effluent spills over three 30-ft. weirs and cascades down steps that break up the liquid into a thin film and spray. Contrary to expectation, no distinct odor, except that of fresh sewage, has ever been detected at this point. The agitation has a distinct advantage. Tests show that there has been an increase in dissolved oxygen saturation of more than 40%, produced by the action of the weirs and steps. It would appear that, given a fresh, weak sewage, the greater the

agitation, the less the tendency for septization and the production of odors. Slime and grease foam coat the walls and appurtenances of the siphon chamber and are hosed as soon as the characteristic musty odor is detected.

Trickling Filters.—The oxidation effected by the dosing tank overcomes the tendency of the liquid distributed on the filter stone by the Taylor nozzles to produce odors, and only slight evidence of such odors can be found to the lee of the filter area. Tests have further shown that there is an increase in dissolved oxygen in the tank effluent affected by the filter distribution piping before the liquid leaves the orifices of the nozzles which increase often amounts to more than 1 part per million.

The black gelatinous growth on the stone surface gives off no odor except when the beds are cut out of service, but this has not been done in two years. Hypochlorite of lime was used successfully during the summer of 1924 to control the development of *Psychoda*. This chemical removed much grease from the nozzle spindles and some of the gelatinous growth on the stone surface. From experience at Schenectady, the use of bleach on troublesome filters is to be recommended.

Sludge Beds.—Great care has been taken to keep all unripe sludge from the drying beds. Small beds, designed to drain the sludge force line, are used for draining test quantities of sludge, as any tendency for the material to give off odors can easily be controlled on the few square feet of these areas.

Conclusion.—All sewage plants have slight odors that are noticeable at the site to the trained observer, and the Schenectady installation is no exception. Odors at the plant are of inconvenience only to those on duty there, but the same odors when carried off plant property are of interest to the public. The prevailing wind at Schenectady blows over the plant in the direction of habitation only 1 000 ft. distant. The topography does not deter the transportation of odors; little obstruction is set up by trees. Thus, the absence of complaint is sufficient proof that the plant is functioning without the production of such odors as would be carried beyond city property.

Most odors reported from sewage plants have little to do with the olfactory senses. They originate in the brain and are a result of over-active imagination. It is indicative of the prejudiced opinion the public has of sewage plants that so many express sincere surprise at the beauty and freshness of the sewage plant grounds and of the clean and inodorous condition of the treatment features. If any particular installation is functioning properly, the speaker would recommend that an invitation be given all taxpayers to visit the works. In no other way is it possible to combat the disgust that most laymen have for things related to the disposal of the liquid wastes of the community.

C. E. Keefer,* Assoc. M. Am. Soc. C. E. (by letter).—The sanitary engineer is beginning to realize more and more the importance of controlling the odors from sewage treatment works. It is necessary not only to reduce the contamination and the pollution of natural watercourses, but also to render the air which one breathes pure and wholesome. This awakened consciousness

* Engr. of Sewage Disposal, Sewer Div., Baltimore, Md.

of the engineer is brought about by at least two factors: First, the public is demanding a more hygienic and satisfactory environment; and, secondly, the engineer himself is continually striving to advance the science of sanitation. For a number of years he has had at his disposal any one of a number of types of sewage treatment that would produce effluents to meet different chemical and bacteriological standards. However, it has been only within the past few years that the problem of the control of odors from sewage work has been treated and discussed before engineering societies. In addition to this, little practical work has been done. As regards the control of odors, sewage works are being designed almost the same to-day as they were ten or fifteen years ago.

The reason for this condition is not difficult to understand. The inherent nature of sewage is such that it will produce an odor and, under many conditions, an unpleasant one. Furthermore, during the course of treatment, the sewage is exposed to the atmosphere, and an excellent opportunity is afforded for the escape of unpleasant gases. One reason odors of any kind are so difficult to control is that little is known about them. As yet, it has not been determined definitely whether they are present in the gaseous or the liquid phase. However, the former assumption seems to be the correct one. Moreover, there is no satisfactory way to measure the degree of an odor. Not infrequently such small quantities of a substance have to be present to produce an odor that it is difficult to make any scientific study of the subject. Until some of these difficulties are overcome—especially determining the phase of the odor and establishing some standard by which odors can be measured—the engineer or scientist will be handicapped in their control and elimination.

If the available data are limited, however, efforts can still be made to reach a solution—even if it is a partial one. In the realm of sewage treatment much can be done to relieve the situation, as Mr. Skinner has ably pointed out, although such relief will not necessarily be complete. It is often possible to locate the sewage works in a sparsely inhabited district so that few people will be affected, to select that type of treatment which will produce a minimum of odors, and to pay particular attention to the details of design so that there will be a reduction in aerial nuisances. However, with the greatest care paid to design and operation, a sewage works consisting of sedimentation and oxidation units of any appreciable size will produce odors that will vary with a number of factors.

Not infrequently persons living in the vicinity of sewage plants will seek redress through the Courts for damages. Such has been the experience of a large sewage works of which the writer has knowledge. Since this plant was first put in operation, approximately $100 000 has been paid for damages caused in part by obnoxious odors. Thus far there seems to be no satisfactory and economical solution for this problem. The actual area of the various treatment units covers several acres, and even if the odors coming from the sewage could be collected and treated successfully, the cost of the undertaking would be prohibitive.

Experiments at Baltimore, Md.—At the Baltimore plant a careful study made by those in close contact with the work has led to the belief that most of the odors come from the preliminary settling tanks. After these tanks have been in service for a short time, a heavy scum forms, which gives off a strong and penetrating odor. If this odor could be eliminated successfully, the situation would be relieved.

With this in mind a series of experiments was begun in the summer of 1924, which consisted in treating the sewage gases with chlorine. One of the preliminary settling tanks was used for this experiment. This tank, which treats the sewage after it passes through bar screens, is approximately 420 ft. long and 103 ft. wide, with a working depth of from 9 to 14 ft. It has a capacity of about 3 800 000 gal. with a detention period of approximately 3.5 hours. The tank is divided into two compartments. The sewage, usually in a stale condition, first enters the smaller compartment, which is 105 ft. long, 103 ft. wide, and from 9 to 11 ft. deep. This compartment was covered with 2-in. tongue-and-groove planking and was thus practically air-tight. At opposite ends of the tank, two small wooden buildings were erected, one of which contained a blower and chlorine control apparatus. There was direct connection from this building to the air space between the top of the sewage and the under side of the wooden covering of the tank. The sewage gases passed into the building, and thence through the blower. The chlorine was applied to the discharge side of the blower which was connected direct to one end of a wooden conduit, or flue, 100 ft. long and 2 ft. square. This flue entered the second building, where an observer could study the treated odors.

The quantity of chlorine used was varied from 5 to 15 lb. per 24 hours, and the volume of gas treated from 630 to 1 480 cu. ft. per min. A number of test runs were made both with the gases from sewage and from the sewage sludge. The tank was operated for a number of weeks so as to produce a thoroughly septic condition and a more intense odor. In order to ascertain the difference between the untreated and the treated gases, the observer first went into the building in which the blower was stationed; after observing the odor, he went into the second building into which the treated gases were passing. Here, he was able to isolate himself from the odors coming from the various parts of the sewage works, and thus breathe only the treated gases, which were being blown from the interior to the exterior of the building.

Observations Made.—One of the most noticeable characteristics of the untreated gas was that it no longer had the characteristic smell of sewage. The odor was considerably less objectionable. Perhaps covering the tank and excluding the sunlight played a part in this new condition. Another interesting change was that little scum formed on the surface of the sewage. This latter condition has prevailed during the warmest summer months up to the present time.

Observations of the chlorinated gases were made by a number of persons, and various opinions were expressed as to the efficacy of the chlorine. Some held that it improved the odor little, if any; others thought that it practically eliminated any unpleasant odor; and still others took an intermediate ground

and contended that the application of the chlorine was a material benefit, but that it had not fully corrected the condition. No definite conclusions were reached.

One of the unfortunate things in connection with any experiment on odors is that there is no satisfactory standard or unit by which they can be measured. There will often be a wide diversity of opinion with reference to any particular odor. For this reason, any conclusions that are reached, will lack a certain definiteness and finality. However, the experiments conducted at Baltimore are felt to be in the right direction, and will probably increase interest in the elimination of odors from other sewage plants. If tests of this character could be conducted at other places, additional data would be available from which more definite conclusions could be formulated.

C. G. Gillespie,* M. Am. Soc. C. E. (by letter).—It is significant of an important exaction in the higher standard which the public is setting up in regard to clean surroundings and clean air, that all the papers presented before the Sanitary Engineering Division at the meeting of January 22, 1925, relate to the odor problem associated with industry and the disposal of putrefying wastes. A relatively untrodden field of endeavor, not at all simple, and fraught with the danger of the imposition of huge expense ultimately falling on the whole public, is opened in the engineering control of odors. In admirable fashion Mr. Skinner presents his own observations and directs engineers to seek out the principles affecting the behavior of odors so that efforts at control may proceed intelligently.

The principles of course are best ascertained where odors from particular sources exist unmixed with those from other sources. This calls for considerable isolation, a condition not common in or near metropolitan areas. Then, too, local temperatures, air movement, variations in the sewage, kind and condition of works, and exactions of the neighboring public, will color experiences throughout the country.

In the absence of any guide to isolation requirements for prospective sewage plants in California, studies were begun in 1923, to ascertain the odor zones around a number of existing and typical plants. This was done by procuring a map of the particular locality showing the homes, roadways, and landmarks, and establishing on the map a number of points surrounding the disposal plant or area, at which points odors in noticeable degree had been experienced by residents. Corroboration of experiences is nearly always possible along public roadways. The extent of odor travel found from these tests is given in Table 11 and a typical nuisance map showing a survey for odors, in Fig. 20.

In California, at least, the observations indicate that odors are most annoying in the summer and in the evening. Daytime inspections are invariably negative as to odors, except at most within a few hundred feet, whereas odors at evening travel many times as far. There is a noticeable tendency for odors to confine themselves to narrow, invisible ribbons of rather uniform intensity stretching out for as much as ½ mile, or more. These ribbons shift in direction and thus establish quite a remote periphery to the odor zone. High

* Director, Bureau of San. Eng., State Board of Health, Oakland, Calif.

or strong winds, of course, dissipate odors rapidly. Low, gentle breezes, especially in the morning and evening, tend to shift the whole body of the nuisance zone only slightly leeward, as indicated by the relation of maximum to minimum nuisance radius. There is a tendency for odorous gases to seek low swales or pockets.

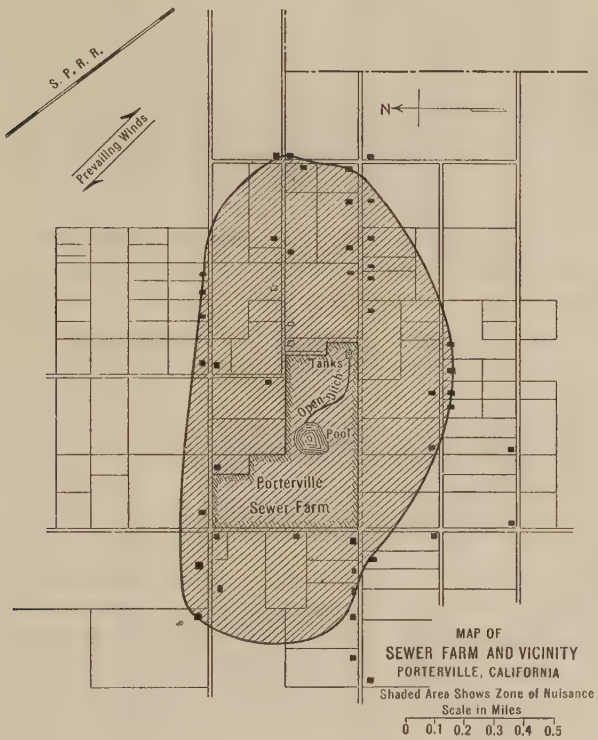

FIG. 20.

The quantity of organic matter, its state of decomposition, and the time or area exposed to the air before it disappears in the ground or is stabilized, markedly affect odor production. Cannery and creamery wastes, perhaps the most prominent industrial wastes in California, produce exceedingly strong odors. The waste from a modest plant is equivalent in its organic matter to the sewage of a large city. Odors are correspondingly intense in all the cases observed. Gas-house wastes impart a heavy but disagreeable odor in sewage, reminiscent of moth balls.

The sulfates in sewage appear to have a marked effect on the production of odor through their conversion to hydrogen sulfide. Along the outfall sewer in El Centro, Calif., intense sulfide odors emanate from the manholes. Sulfates in the 3-mile outfall drop gradually and uniformly from 330 parts per million ½ mile below El Centro to 160 parts per million at the Imhoff tank, and 155 parts per million in the tank effluent. It is curious to note that the sulfate-

TABLE 11.—Results of Odor Surveys Around Certain Sewage Treatment Plants and Disposal Areas in California.*

Place.	Population.	Treatment.	Disposal.	Nuisance Radius, in Miles.			Character of sewage.
				Average.	Maximum.	Minimum.	
Hollister	3 000	Raw sewage	Sewage farm	0.75	1.25	0.25	Contains gas-house waste and cannery waste
Vacaville (South Farm)	1 200	Raw sewage	Sewage farm	0.50	0.75	0.25	Domestic sewage
Vacaville (North Farm)	1 200	Septic tank	Sewage farm	0.75	1.00	0.25	Domestic sewage
Santa Rosa	13 000	Septic tanks	Sewage farm	1.00	1.25	0.25	Contains cannery, tannery and gas-house wastes
Fresno	55 000	Septic tanks	Sewage farm	2.00	2.50	1.50	Principally domestic sewage.
Selma	3 500	Imhoff tank	Sewage farm	1.75	3.00	1.00	Contains excessive cannery waste
Clovis	1 000	Septic tank	Sewage farm	0.37	0.50	0.25	Domestic sewage
Exeter	2 000	Imhoff tank	Sewage farm	0.62	0.75	0.50	Domestic sewage
Lemoore	1 500	Septic tank	Sewage farm	1.00	1.25	0.25	Domestic sewage
Porterville	4 500	Septic tank	Sewage farm (sandy)	0.75	1.00	0.50	Domestic sewage
Lindsay	2 800	Septic tank	Sewage farm	0.50	0.75	0.25	Domestic sewage
Corcoran	1 000	Imhoff tank	Sewage farm	0.50	0.75	0.25	Domestic sewage
Hanford	6 500	Imhoff tank	Sewage farm	1.00	1.50	1.25	Contains much cannery waste
Visalia	6 500	Raw sewage	Sewage farm	1.50	1.75	0.75	Contains much gas-house and cannery waste
Reedley	3 500	Sprinkling filter	Kings River	0.37	0.75	0.25	Fresh domestic sewage
Kingsburg	1 200	Sprinkling filter	Kings River	0.75	1.25	0.50	Septic domestic sewage
Dinuba	3 500	Septic tank	Sewage farm	1.25	1.50	1.00	Domestic sewage
Dinuba	3 500	Sprinkling filter	Drain ditch	1.00	1.50	0.75	Domestic sewage
Paso Robles	2 000	Imhoff tank	Salinas River (bottoms)	0.37	0.50	0.25	Domestic sewage and hydrogen-sulfide swimming pool water
Tulare	3 500	Septic tank	Sewage farm	1.5	2.00	1.00	Domestic sewage and much milk factory waste
Sonoma	1 200	Septic tank	Sewage farm	0.75	1.50	0.50	Domestic sewage

* By California State Board of Health, Bureau of Sanitary Engineering, C. G. Gillespie, Director, dated January 2, 1925.

consuming organisms are reported to accumulate in this outfall until it becomes nearly choked. Application of copper sulfate at the head of the outfall destroyed and loosened the growth, allowed it to float down the outfall, and temporarily corrected the odor.

At Coalinga, Calif., where the sulfates in the water supply have approximated 1 000 parts per million, a crust of precipitated yellow sulfur has formed below the water line in the outfall sewer beyond the septic tank and the concrete of the tank itself is practically destroyed, probably due to the attack of associated acids. At the outlet of the tank intense odors of pure hydrogen sulfide are given off.

Long force mains between pumping plants and sewage treatment works of small towns in California contribute noticeably to the production of odor for the reason that over-size pumps must be used to prevent clogging and pipe lines are correspondingly large. The time of passage through this section of the sewer system may be as much as five times that through a gravity sewer of the same length, and the sewage not only ages as much as 3 or 4 hours in them, but becomes charged with putrefactive gases given off in the sewer.

For the same reasons, flat sewers, and sewers in which the manholes have a depressed bottom ostensibly for intercepting sediment, have intensified the production of odor. The writer's experiences with high groves of sheltering trees, reinforced by a 30-ft. levee, is that these barriers failed to confine the odors. One experience with the housing of sewage treatment works was not satisfactory. This was over a small Imhoff tank and sprinkling filter at Los Gatos, Calif. The housing so intensified the temperatures in the sprinkling filter as to interfere seriously with its results. The housing was opened and the plant subsequently abandoned because of the odor annoyance to neighbors.

Experience at Dinuba, Calif., where a sprinkling filter and Imhoff tank superseded a septic tank and sewage farm, tends to show that the zone of odor was practically the same in both cases.

As to the activated sludge process the writer has made observations on only two plants, at Lodi and at Pasadena, Calif. The Lodi plant treats the sewage of a town of 7 500 people, including gas-house waste, and in summer also the waste from a 50-ton peach and tomato cannery. The sewers in Lodi are laid on extremely flat grades. Sludge is spread on sedimentary soil overlying hardpan and when dry is plowed under as fertilizer. Odors are not noticed at a residence 500 ft. away at any time, nor have they even been noticed beyond a few feet from the plant or from the sludge area. Returning the sludge from the clarifiers to the sewer ahead of the fine screen, lessened the odors in the screen room, but caused more watery screenings.

The Pasadena plant treats a strong domestic sewage for a population of about 100 000. The worst fault of this plant is that it is undersized for a rapidly increasing load. Odors, however, were not a factor beyond 1 000 ft. or more, until deep lagooning of sludge was tried.

There seems to be a singling out of sewage odors for complaint by the neighboring public, probably through the old fear that sewage gases are dangerous to health. It seems to the writer that the public needs to know that

sewage odors are merely a nuisance, more or less annoying and discomforting, not essentially different from the odor from corrals, pig pens, factories, fertilized fields, and the like. In equity, although one may be more intense or more widely annoying than the others, they are all nuisances differing only in degree. Unless there is considerable tolerance and this noticeable movement for cleaner air proceeds prudently, a financial burden altogether too heavy may easily result. In the final analysis the expense shifts to the whole public. Agitators may easily become inimical to the best public interest. A real odor nuisance generally depresses property values. If the total cost of abating all the nuisances responsible for that particular damage even approximates the estimated damage, it seems only logical that correction of the odor is in order and this principle may afford some means of judging the merit of a proposition to control odors.

T. Chalkley Hatton,* M. Am. Soc. C. E.—The speaker would like to challenge one statement of Mr. Skinner, in which he says:

"Lagooning undigested sludge is likely to produce odors, for either scum may form or there may be insufficient water to cover the sludge, which will then putrefy and give off odors.

"In general, lagooning should only be adopted in winter or in remote locations where no nuisance will be occasioned to neighbors."

At Houston, Tex., a nuisance has not resulted from the lagooning of activated sludge either in winter or in summer and little or no scum has formed on the surface of the liquor after several years of operation.

At several sewage treatment plants in England, undigested sludge has been lagooned without creating a material nuisance which might be considered detrimental to the surrounding neighborhood. The large and numerous digestion tanks at Saltly in the Manchaster plant, which contain highly concentrated undigested sludge, could not in July be termed offensive judged from 200 ft. away especially after the formation of the heavy top scum.

It is doubtless true that while the undigested sludge is being transported from one tank to another, the sulfureted hydrogen escapes and creates an objectionable odor but when the sludge becomes quiescent the odors arising from its decomposition, when in the presence of water, are scarcely perceptible a few hundred yards away at most.

N. E. Loomis,† Esq. (by letter).—In carrying out most of the suggestions made by Mr. Weston, the writer feels certain that sanitary engineers will meet with hearty co-operation from the oil industry. In fact, in the largest and most up-to-date refineries they have already been carried out. This is for the reason that the escape of odors is immediately connected with other losses which the efficient refinery wishes to avoid.

For example, Mr. Weston has emphasized the importance of collecting the gases from the various distillation processes and burning them under stills, in order to obviate odor troubles and at the same time to effect fuel economies. As an alternative the scrubbing of gases with a solvent oil was

* Chf. Engr., Sewerage Comm., Milwaukee, Wis.

† Director, Experimental Div., Standard Oil Co., Elizabeth, N. J.

mentioned with the objection that the gasoline recovered was so "wild" as to escape subsequently and thereby create a nuisance. As a matter of fact, in most of the first-class refineries all gas is collected from the distillation operations, scrubbed to recover the stable gasoline that it always contains, and then the dry gas is burned under boilers or stills. There are numerous methods for insuring that the recovered gasoline be free from dissolved gases which later might cause odor trouble. It frequently happens that the recovery of gasoline alone in such a manner pays a substantial profit in addition to having the fuel value of the dry gas, which value may amount to more than 20% of the total fuel consumed in the entire refinery. The combined operation of recovering the gasoline from the gas and using the dry gas as fuel represents an economy over wasting the gas that a large refinery cannot afford to neglect.

Mr. Weston recommends the use of a vacuum system on tankage. There are two kinds of tankage used in refinery operations—storage tanks for crude and refined products (which may be as large as 80 000 bbl. in capacity), and working tankage. The working tankage is smaller in size and, as a rule, comprises a much smaller number of tanks than the storage tankage. It is often feasible to tie the working tankage into a vacuum system as recommended, but the present construction of most storage tankage would make this impracticable. Further, the escape of gases from storage tanks can be minimized in other ways so as to make it unnecessary.

Odors from the burning of oil under boilers and stills should not be objectionable provided complete combustion is obtained; here again there is a community of interest between the general public and the oil refiners. In many refineries it is the custom to keep a crew of men constantly studying the combustion conditions of the various pieces of equipment. Appearance of smoke at the stacks is an indication of improper operation.

Mention has also been made of the odors resulting from treating oils with acid and from the concentration of the recovered weak acid. In treating, the use of tight agitators and the mechanical mixing of oil and acid prevents the escape not only of odors but also of valuable fractions of the oils. The odor difficulties encountered in acid concentration are being minimized both by the use of proper types of concentrators and also by the proper conditioning of the weak acid to eliminate organic material.

In trying to eliminate odors from oil refineries sanitary engineers are fortunately facing a different situation from that in some other branches of industry. With the refineries they are dealing not with the prevention of a nuisance which can be corrected only at a monetary loss, but rather with a condition in which the economics effected will actually pay a profit in almost every case cited. This higher operating efficiency is certainly the strongest argument which can be used by sanitary engineers and public health officials in forwarding the work in which they are primarily interested. By proper co-operation based on the community of interest, sanitary engineers and refinery managers should be able easily to correct whatever troubles actually exist. In no case, however, do American conditions resemble in the faintest

manner the picture that has been drawn of Russian conditions. The efficiency which has always maintained the American refining industry in a position of unchallenged world leadership would make such conditions in the United States absolutely impossible.

Edward Wright,* M. Am. Soc. C. E.—The importance of the detection and elimination of odors from oil refineries is perhaps more fully realized by a comparatively small number of sanitary engineers in Eastern Massachusetts, in the vicinity of Providence, R. I., and certain districts in New York State and New Jersey, than by the profession in general. The number of complaints on account of odors from the refining of high sulfur oils since the World War has been unparalleled in the recent records of the Massachusetts Department of Public Health.

To indicate the size of the oil refining industry, it may be said that one of the refineries in Eastern Massachusetts has been the heaviest shipper on the New York, New Haven and Hartford Railroad System. Although the number of persons engaged in the industry is not great, an immense amount of capital is invested in the 500 to 600 refineries in the United States, and the industry is an increasingly essential one.

Soon after the World War, the New England refineries used great quantities of Mexican crude oil which contained 1.5 to 6% sulfur. More recently, and simultaneously with greater knowledge and improvement of odor control apparatus, considerable quantities of crude oil rarely exceeding 0.5 of 1% of sulfur have been shipped from California and Texas and from other fields. Extensive prospecting is now under way in Venezuela where crude oil having a sulfur content from 1 to 3½% is being obtained in increasing quantities. If large quantities of this crude oil are used, the objectionable conditions which arose with the use of Mexican crude may occur again unless adequate control devices are operated. Not all the sulfur is removed during the refining process; in fact, fuel oil may contain 3 to 4% of sulfur, and the speaker has noted hydrogen sulfide odors from the combustion of Mexican fuel oil which were more marked than the odors from a poorly managed sewage disposal works situated adjacent to the power plant. This indicates that the time may come when it will be necessary to remove some of the sulfur, possibly by chemical means, from certain fuel oils.

It may be of interest to describe briefly some of the methods and difficulties of operating odor-control devices that have come to the speaker's attention in examinations for the Massachusetts Department of Public Health. The installation of odor-control devices, like that of sewage disposal works, is only the beginning. Painstaking operation of the devices is essential. The operating force under which these various gas systems are controlled in one of the larger and more complete refineries in Massachusetts consists of ten men: a supervisor and a night supervisor; an experienced man and two helpers employed in the inspecting, cleaning, and changing of screens in the various gas lines; an experienced man and a helper employed in the inspection and maintenance of the water seals and recording instruments; and three gas-

* Asst. Engr., Massachusetts State Dept. of Health, Boston, Mass.

system operators working in three shifts, who make hourly inspections of the gas-collecting systems and the plant in general. Detailed reports of the inspections are submitted in writing or in tabular form to the supervisor at the end of each 8-hour shift, and the essential data are subsequently submitted to the management.

In the complete refinery, there are eight to ten recording instruments on the pipe systems for collecting non-condensable still-gas together with a number of additional instruments for determining temperatures and other data that are of value to the refinery, but of no particular significance in the odor elimination problem. Parts of the instruments must be renewed from time to time because of the corrosive effect of the gases. The records not only show the quantity of gas, but also immediate evidence of any defect in the gas collection or gas-pressure system, such as leaks or the formation of deposits. The instruments are placed so as to be visible, particularly to the operators of the gas exhausters.

In a refinery handling 15 000 to 20 000 bbl. of crude oil daily the non-condensable still-gas may amount to 1 500 000 cu. ft. per day, but the quantity varies greatly from hour to hour even when the stills are operated continuously.

The quantity of air in the non-condensable still-gas is estimated three times a week at one of the refineries in Massachusetts, and determinations are made less frequently for hydrogen sulfide and other constituents. The quantity of air varies from 10 to 35% by volume in the low-pressure still-gas, and when a weekly run of about one-third Mexican and two-thirds Californian crude is being used, the hydrogen sulfide varies from 3 to 15% by volume.

The gas pressure lines leading to the boilers are provided with one or more water seals which must be kept under constant supervision, with a seal of 2 in. of water. Running water is usually provided in these seals to compensate for evaporation, and care must be exercised to prevent freezing.

In disposing of the gases of evaporation from the crude oil storage tanks an equilibrium in pressure is provided on the tanks while they are being filled, whereas on the storage tanks for hot oil a constant vacuum of ¼ in. to 3 in. of water is maintained. U-tubes are provided at various points throughout this system, and in the winter these tubes are filled with a solution of gas-oil to prevent freezing. The liquid in the U-tubes is usually colored with red ink to facilitate reading, and readings are made hourly and properly recorded.

Thirty-mesh Monel metal screens are installed on the gas-line outlets of all the oil tanks and containers, mainly for fire protection. The screens are given several inspections weekly, which indicate that the surfaces sometimes quickly become coated with deposits, largely of sulfur. The life of these screens averages not more than three weeks and proper management requires that they be kept in good condition in order to prolong the periods between cleaning and renewal of the gas lines. At one of the refineries in Massachusetts, 3-in. gas lines on the hot-oil, storage-tank systems have recently been replaced with 6 and 8-in. lines because of deposits. The gases of evaporation are passed through suitable seals in which running water is maintained. The water seals on top of the tanks require inspection twice daily.

The quantity of air in the gases of evaporation, which is estimated three times weekly, varies from 40 to 80 per cent. Additional determinations are made less frequently for hydrogen sulfide and other constituents.

The maintenance of the odor-control devices in the plant for chemically treating raw gasoline is also troublesome, particularly because of the acids contained in the gases. All parts of this apparatus are inspected frequently for leaks.

Odors often result from deterioration of the metal parts of refining apparatus allowing the escape of the contents. Corrosion and deposits made up largely of sulfur present great difficulties in operating the gas-disposal systems at oil refineries, particularly in the non-condensable gas lines from the low-pressure stills where the gas contains as high as 35% of air. Corrosion is less marked in the high-pressure still lines where air is not present. The mixture of the air and gas with sulfur compounds readily corrodes wrought-iron pipe so that its average life is not more than three to four years. The mixture of the gases of evaporation from various grades of petroleum products and air also corrodes the tops of the metal tanks so that it is necessary to replace them every three to five years. In gas-holders for storing the non-condensable gas, the corrosion is also marked and careful inspections and renewals of parts of the holders are necessary in order to prevent leaks.

Regular inspections are made of the still settings to determine the presence of breaks in the walls due to the contraction and expansion of the stills, and when the stills are used on the batch process, as is necessary when the heavy crude oils are refined down to coke, very careful attention is necessary to prevent leaks and to provide good combustion of the fuel beneath the stills.

The management of one of the refineries in Massachusetts requests the salesmen and others to make such observations in the locality about the refinery as are reasonable and to call up the management if offensive odors are noted. A representative of the Odor Control Department is on hand at all times to make observations in the field concerning complaints and to determine and correct the cause.

Samuel A. Greeley,* M. Am. Soc. C. E. (by letter).—Mr. Lewis properly emphasizes the need for beginning studies at the garbage pail itself and including both collection and disposal for the control and proper elimination of odors.

Mr. Osborn comments on the relation between the location of a garbage disposal plant and the cost of haul. This is undoubtedly an important item. As indicated in the paper,† zoning boards have recognized certain odor-producing industries by outlining so-called nuisance and semi-nuisance districts. Presumably the amount of odor control for such industrial establishments is related somewhat to their location. Just how far such practical considerations should influence the design and cost of a garbage disposal plant must be determined for each special case. The writer has investigated such a situation in a city of 140 000 population. An old established site, well isolated, was available for the garbage disposal plant. The use of another site would have

* (Pearse, Greeley & Hansen), Chicago, Ill.

† See p. 361.

permitted the collection work with one less wagon, effecting a reduced annual cost amounting to about $5 000. However, it was decided that the security of the existing site against nuisance hazards was worth the extra cost.

Mr. Osborn's comments on the fundamental features of design and his statement that engineers are not using available experience, are sound. However, records of operating experience with garbage disposal plants are not as well advanced as other branches of sanitary engineering work. Undoubtedly, a great deal of such experience has been had, but relatively little of it has been published in a definite way, as yet, with reliable yardsticks. In comparison with the large sums that have been expended by municipalities in testing sewage disposal processes, there is much yet to be done in the field of garbage disposal. Mr. Osborn's statement, therefore, that the disposal of garbage in a sanitary manner is a function requiring study on which municipal officials and engineers should look with the same interest as they do on other municipal problems, is a good summary of the situation.

John F. Skinner,* M. Am. Soc. C. E. (by letter).—The writer appreciates the value of discussion elicited from engineers in charge of different types of plants and illustrated by conditions in widely separated localities.

Mr. Cohn refers to the sour odor "caused by the fermentation of the great quantities of mash that clog the gas vents." At the Irondequoit plant at Rochester, N. Y., "considerable quantities of grain are found in the grit, the probable source being the wastes from home-brewing processes." This material is deposited with the grit and if promptly removed causes no offense. This is one of the reasons why a small grit chamber may be desirable in a plant limited to the treatment of sanitary sewage. Mr. Cohn's observations indicate that care and cleanliness about the plant remove most causes of complaint.

Mr. Keefer's work at Baltimore, Md., including the confining of gases and their treatment with chlorine, is most interesting and points the way to further experimentation. It is in line with the writer's suggestion.

Mr. Gillespie's odor surveys are excellent in furnishing comparative results which may be studied in the light of location, exposure, prevailing winds, type of sewage, and care in operation. His statement, "daytime inspections are invariably negative as to odors, except at most within a few hundred feet, whereas odors at evening travel many times as far", corresponds with the writer's observation and his explanation of the phenomena due to convection.

The writer has assumed that any considerable quantities of putrefying industrial wastes should be treated before admission to the public sewers. In general, the expense of such treatment should be borne by the interests involved rather than by the general public.

Mr. Gillespie's observations at El Centro, Calif., indicate how a trained and observant operator may relieve an acute condition by a specific remedy. The plowing under of activated sludge at Lodi, Calif., and its local use as fertilizer, is doubtless the best solution for a small plant suitably situated.

Mr. Hatton's criticism anent lagooning of activated sludge is interesting. He states that at Houston, Tex., little or no scum has formed, while at Saltley

* Cons. Engr.; Deputy City Engr., Rochester, N. Y.

in the Manchester, England, plant he refers to the formation of heavy top scum.

J. C. McVea, M. Am. Soc. C. E., City Engineer of Houston, writes that his sludge lagoons are 18 in. to 10 ft. deep, and of various sizes up to nearly 1 acre in area:

"No appreciable amount of scum forms on the surface * * * and it will be necessary for them [lagoons] to stand several months before they are entirely dry. Odors are not noticeable during the normal operation of the lagoons, but upon allowing them to stand for several months and to dry out a very offensive odor is created upon again filling with sludge unless the old material is entirely removed."

This is with a range of temperature from 50 to 105° Fahr.

Mr. Gillespie writes that at Pasadena, Calif., the activated sludge was lagooned 2 or 3 ft. deep in a sandy river bottom:

"The sludge soured badly and made a terrific nuisance, reaching about 6 000 ft. away where it made a nuisance to some 7 000 people. Examination of the beds seemed to indicate that they remained sour for at least a month * * *. No scum formed on the surface of the lagoon. It was rather a pasty sludge. There was a thin, dry crust which was evidently not sufficient to confine the odors."

The lagooning has now been discontinued and the present practice is to coagulate the sludge with alum, dry on an Oliver filter, and bury in deep trenches. The latitude of Pasadena is 34° N.

At Houston, the lagoons are operated continuously at considerable depth practically as open septic tanks. In Pasadena the odor from sour sludge in shallow lagoons became unbearable. Odors from lagooning apparently depend on the condition of the sludge, the temperature, the depth of supernatant water, the formation of scum, and the method of operation. The writer, therefore, feels justified in his statement that, "in general, lagooning should only be adopted in winter or in remote locations where no nuisance will be occasioned to neighbors."

Robert Spurr Weston,* M. Am. Soc. C. E. (by letter).—Mr. Loomis has done well to call attention to the necessity for co-operation between oil refiners and the public and to the economies resulting from proper odor-preventing devices. Regarding the use of a vacuum system on storage tanks, the writer still believes it to be an excellent method for the control of odors from these structures and one which is best adapted to a critical environment where the minimizing of the escape of odors rather than the prevention thereof does not suffice.

The use of oil for scrubbing is of course sound scientific practice and ought to produce no odor. The writer cannot presume to approve or disapprove; he has seen cases where its operation was faulty. This again emphasizes the equal importance of good construction, good inspection, and careful operation of all odor-preventing devices.

Naturally, the word picture of Baku, Russia, quoted by the writer, will never be exhibited in the United States. It stands in contrast to the condition toward which American refinery practice is growing.

* Cons. Engr. (Weston & Sampson), Boston, Mass.

Mr. Wright's emphasis upon the necessity for vigilance in inspecting instruments, screens, traps, and other devices so subject to corrosion, is a point well made.

After all the oil industry is as necessary to the community as any other purveyor to civilization, and it is particularly incumbent upon sanitary engineers to assist in those adjustments of plant, of regulations, of methods of control, and of public attitude, which are necessary to maintain the rights of all with due regard to the rights of every one—refiner, petroleum user, navigator, bather, pleasure seeker, and the ordinary air-breathing householder.

Paper No. 1580

THE ST. LAWRENCE WATERWAY TO THE SEA*

By Francis C. Shenehon,† M. Am. Soc. C. E.

With Discussion by Messrs. H. de B. Parsons, H. C. Sadler, F. P. Williams, Thomas H. Hogg, L. C. Sabin, Gardner S. Williams, E. P. Goodrich, David B. Rushmore, Maurice W. Williams, L. H. Hart, A. Lindblad, Walter M. Smith, W. M. Black, G. B. Pillsbury, L. F. Harza, Elliott J. Dent, Kenneth L. De Blois, C. S. Riché, E. G. Walker, and Francis C. Shenehon.

Synopsis

The writer assumes the only substantial justification for a deep waterway connecting the Great Lakes with the salt seas is the deep penetration of the continent to Duluth, Port Arthur, and Chicago. The navigable right of way of the whole Great Lakes System, therefore, is involved in the discussion.

The 1924 project-drafts in Lakes Erie, Michigan-Huron, and Superior with the connecting rivers, are 20 ft. The waterway to the sea contemplates initially 25-ft. and ultimately 30-ft. drafts.

The St. Lawrence River is the geological avenue to the sea through which outflow the surplus waters of the Great Lakes. This river is, therefore, the natural avenue for a navigable waterway to the sea. The water itself, with a volume of 220 000 sec-ft. and a descent of over 220 ft. from the level of Lake Ontario to Montreal, is one of the great power resources of the world. The writer assumes that the development of water power co-ordinately develops and subsidizes a navigable waterway.

This paper describes the Port of Duluth and the various navigable ways through Lake Superior, St. Marys River, Lake Huron, the St. Clair and De-

† Cons. Engr., Minneapolis, Minn.

troit Rivers, Lake Erie, through the Welland Canal descending over the Niagara Escarpment 326 ft. to the level of Lake Ontario, and then through Ontario and the Upper St. Lawrence to the Rapids Section of this river. This section, beginning at the Galops Rapids and terminating at the foot of the Lachine Rapids at Montreal, is the locus of the great constructions contemplated at an initial cost exceeding $250 000 000. Little detailed description of the development of the Rapids Section contemplated in the report of the International Joint Commission of 1921 is embodied; but some general principles involved in the best co-ordination of navigation and water power are suggested.

A new International Board of Engineers is studying the report of the Government engineers of 1921, having in mind a review of the earlier conclusions. It has seemed appropriate, therefore, to devote the major portion of the paper to those elements of the problem not within the purview of the report.

The water supply tributary to the St. Lawrence is fully discussed and works are suggested to increase the dependable volume of flow.

Two routes from the Great Lakes to the sea investigated by the Board of Engineers on Deep Waterways in 1900, are touched upon. The route by the way of Oswego and the Mohawk to the Hudson, thence to the Port of New York, was preferred in 1900. Since that time, the near completion of the Welland Canal and the desirability of building at least the International Section of the St. Lawrence River Waterway, make preferable a route to the sea through the St. Lawrence River to the foot of Lake St. Francis, thence descending to Lake Champlain and through the Hudson River to the Atlantic.

It is shown that the deeper drafts in the Great Lakes necessary for a waterway to the sea, are also economically desirable for the immense existing internal navigation. It is shown that regulating works, in addition to those already built at the foot of Lake Superior, may be constructed at the head of the St. Clair and Niagara Rivers. These works will raise the lake levels and diminish the excavation needed for 25-ft. drafts.

The regulating works recommended will convert Lakes Superior and Michigan-Huron into vast storage reservoirs as aids to water power in the Niagara and St. Lawrence Rivers, stabilizing the flow and adding 20 000 sec-ft. to the volume of prime flow. The fact is emphasized that in a state of Nature it takes several years for available storage water in Lake Superior to be transmitted for power use in the Niagara and St. Lawrence Rivers; whereas with a complete series of manually controlled regulating works the equivalent of Lake Superior water may be instantaneously made available in these great power streams. And conversely the equivalent of excess water supply in one of the lower lakes, Ontario, for example, may be instantaneously transmitted to the Superior Reservoir or to the Michigan-Huron Reservoir.

Water power at Niagara Falls is touched upon as competitive in a limited market with St. Lawrence power.

The international aspects of the various constructions are discussed, and certain suggestions made for desirable elements to be incorporated in a new Boundary Waters Treaty between Great Britain and the United States.

The St. Lawrence Waterway to the Sea may be narrowly visualized as the St. Lawrence River improved for 25 or 30-ft. navigation between the smooth, stately river at Montreal, and the smooth, stately river above the Galops Rapids. In the intervening 115 miles, the river descends roundly 224 ft. and has a normal flow of 230 000 cu. ft. per sec. Under average river-stage conditions, ocean liners of 30-ft. draft penetrate the continent as far as Montreal—1 000 miles inland from the open Atlantic—making Montreal one of the great ports of the world. Advancing this inland travel of ocean liners to Toronto, near the west end of Lake Ontario, serves no adequate navigational purpose. The Great Lakes still reach nearly 1 000 miles inland after climbing, by locks and canals, 326 ft. up and over the Niagara Escarpment and entering the foot of Lake Erie. The east end of Lake Erie, with Buffalo as its principal port, is really the water origin for present west-bound commerce and the water terminal for east-bound cargoes.

In the largest sense the St. Lawrence Waterway to the Sea must be visualized as the right of way leading to the Gulf of St. Lawrence from Duluth and Port Arthur, near the head of Lake Superior, and from Chicago, at the extreme south end of Lake Michigan. Deep penetration of the continent is the only adequate justification for great expenditures in the name of navigation. (See Plate III and Fig. 1.)

The St. Lawrence Waterway to the Sea contemplates deep-draft navigation—perhaps 25-ft. depths first, with 30-ft. drafts some decades later. The present navigation scheme for Lake Erie, and the rivers and lakes westward to Chicago, Duluth, and Port Arthur, is for 20 and 21-ft. depths—20 ft. in sheltered channels with soft bottom, 21 ft. where exposed to the surge of wave action and in rock channels. The Deep Waterway to the Sea, therefore, must include, as an essential part of its project, the securing of better depths in all artificial channels, harbors, canals, and locks which deep-draft vessels may need to traverse in the whole Great Lakes System. These depth betterments will be secured by two methods: First, by the comprehensive method of the maintenance of higher lake and river levels; and, second, by the piecemeal, localized method of dredging in trunk-line channels and canals and in important harbors. In many cases both methods will be necessary—the volume of dredging being diminished by the prism gained by the maintenance of higher water-surface levels.

Near Available Mileage

One of the notable things in this waterway project is the relatively large mileage already available for 25-ft. drafts; the mileage which will become available by the maintenance of higher water-surface levels; and the major projects, small in mileage but large in cost, already advancing toward com-

pletion. The project as a whole awaits only the breaking through of a few impediments and the construction of works at the heads of the outflow rivers. The penetration of the principal impediment in the Rapids Section of the St. Lawrence will be eventually subsidized in whole or in part by the water power simultaneously developed.

The mileage of the vessel tracks of the Great Lakes is infinite and the mileage of the principal avenues or trunk lines is very considerable. Confining attention to the trunk line with Duluth as the initial westernmost port of the waterway and a point 1 000 miles below Montreal as the eastern gateway to the ocean, the total trunk-line length is 2 340 miles—with Liverpool still 2 200 miles away across the Atlantic. The mileage available after lake-level maintenance is effective and the Welland Ship Canal completed is given in Table 1.

The mileage requiring improvement, dredging, or cleaning up of obstructions, is about 9½% of the 1 338-mile vessel track from Duluth to Montreal; and about 5½% of the 2 341 miles of trunk-line waterway between Duluth and Belle Isle Straits. Outside this trunk line is the right of way of the salt seas encircling the globe.

TABLE 1.

Section.	Near available, miles.	Requiring improvement, miles.
Duluth to ship locks, St. Marys River	391	3
Ship locks, St. Marys River, to Detour	30	20
Detour to head of St. Clair River	213	3
St. Clair River	37	3
Lake St. Clair	10	8
Detroit River	16	11
Lake Erie to entrance of Welland Canal	227	3
Welland Ship Canal completed about 1930	26	0
Lake Ontario to Tibbetts Point	156	0
St. Lawrence River to Galops Rapids	66	3
St. Lawrence, Galops Rapids to Montreal	40	72
St. Lawrence, Montreal to Atlantic	1 003	0
Totals	2 215	126

For practical use of the waterway, the mileage of tracks in the principal harbors utilizing deep drafts must be added. Mostly the mileage given in Table 1 and mostly the work in harbors and harbor entrances are in sheltered areas where dredges may work in all weather conditions.

Cost of Improvements

The aggregate yardage to be removed is comparatively small to change 20 and 21-ft. channels, based on extreme unregulated low-water levels of the Great Lakes and interlake rivers, to 25 and 26-ft. channels, based on higher regulated lake and river surface levels. The channel depths which will come with maintained surface levels will be for the most part 22 and 23 ft. between Duluth, Port Arthur, Chicago, Detroit, Buffalo, Toronto, Prescott and Ogdensburg. The remaining 3 ft. of depth for 25 and 26-ft. channels will be secured

by cleaning up some of the channels and by dredging to an additional depth of 3 ft. in others. The volume in a mile of prism, 3 ft. thick and 300 ft. wide, is less than 200 000 cu. yd. One-half, at least, of the 50 miles of the Great Lakes is in channels with soft bottoms, as in Lake St. Clair; a large fraction is in glacial drift formations with boulders, as in St. Marys River above the locks; while a comparatively small mileage is in sand rock or limestone formations, as in the Neebish Channels in St. Marys River, in St. Marys Falls Canal and in the Lower Detroit River. Harbor channels are for the most part in soft materials. Only the major harbors of the Great Lakes need improvement for 25 and 26-ft. drafts.

The cost of deepening St. Marys River represents the largest item of dredge work. Louis C. Sabin, M. Am. Soc. C. E., U. S. Civilian Engineer in charge of the construction, maintenance and operation of the locks, canals and channels of St. Marys River (1924), has provided the following unit prices for submarine excavation:

	Pre-war.	1924.
Earth per cubic yard.....	$0.11 to $0.15	$0.18 to $0.30
Medium rock per cubic yard....	2.00	3.00
Hard rock per cubic yard.....	3.00	4.00 to 4.50

In the West Neebish Channel, excavated in the dry in a coffer-dam, the prices, 1904 to 1907, were $1.36 per cu. yd. for limestone rock and $0.56 for earth. Pre-war prices in the Detroit River compiled by Charles Y. Dixon, M. Am. Soc. C. E., for shallow cuts in submarine rock and glacial drift, indicate about $2.15 per cu. yd. At present this might cost $3.50 per cu. yd., and is comparable with the work still necessary in the Detroit River and in the rock and glacial drift sections of the channels of the Great Lakes and rivers above the Galops Rapids of the St. Lawrence River. Taking into account the sections of soft bottom in Hay Lake and Mud Lake of St. Marys River and the fine sand in Lake St. Clair, the cost of improving all trunk-line channels above the Galops Rapids to Chicago, Port Arthur and Duluth, may be between $30 000 000 and $40 000 000. Adding to this sum, the cost of breakwaters, regulating works, and navigable passes at the head of the St. Clair River, $10 000 000; and regulating works and excess-capacity channels in the Niagara River, $10 000 000; it appears that the total cost of 25 and 26-ft. navigation will be somewhat less than $70 000 000.

Benefits

These betterments will serve not alone the commerce seeking an outlet to the salt seas and seeking to pierce deep into the continent from the salt seas, but will serve also the inland commerce now utilizing, on impaired drafts, the right of way of the Great Lakes—with a volume of 100 000 000 tons in a maximum year. It will appear as this discussion develops that the regulating works already built and in operation at the outlet of Lake Superior and those proposed by the writer for the head of the St. Clair River, will make available for water-power volume and continuity in the Niagara and St. Lawrence Rivers

the vast storage reservoirs of Lake Superior and Michigan-Huron; and that the regulating works proposed for the head of the Niagara River will nearly double the volume of water permissible for power use at Niagara Falls, will permit the peak-load use of inefficient plants, and will solve some difficulties coming with the season of ice. As regulating works are part of the proposed St. Lawrence River development, only this mention of the works in that river, as the lowermost link in the series, is at this point desirable.

Scope

This discussion has three phases:

First.—The internal commerce of the Great Lakes as it now exists as an economic asset of two nations, with the physical limitations which handicap it, and the proposed engineering remedies.

Second.—The outlets to the salt seas existing and contemplated, including the St. Lawrence avenue.

Third.—Water power at Niagara Falls and on the St. Lawrence River as an economic asset of two nations, with the physical and international elements which handicap it—and the engineering and international remedies.

It appears obvious that if an expenditure of $70 000 000 in the Great Lakes System above the Galops Rapids, in addition to the new Welland Ship Canal now nearing completion (1924), did not serve as a paying investment for the movement of the 100 000 000 tons of fresh-water cargoes, it might be a venture hinging on a problematical salt-water commerce; and if the expenditure of $200 000 000 or $300 000 000 to make possible a problematical volume of commerce between fresh water and salt water, did not co-ordinately bring into use upward of 4 000 000 e.h.p. to enrich two nations, the St. Lawrence avenue to the sea might be forgotten for a generation or more. If, however, the expenditure of $70 000 000 in the Great Lakes System above the Galops Rapids serves economically the fresh-water commerce of the United States and Canada and, at the same time, vitalizes and multiplies the water power at Niagara Falls and on the St. Lawrence River, it ceases to be a doubtful venture; and if the water-power development of the St. Lawrence subsidizes the cost of the navigable avenue of this river above Montreal, the St. Lawrence Waterway to the Sea will not need to be forgotten for a generation.

These three things—the right of way of the Great Lakes, the various avenues to the sea, and the water power generated by the excess outflowing waters of this vast drainage basin—are the elements to be discussed.

Standards

The right of way of the Great Lakes, between Duluth, Port Arthur, Chicago and Lake Erie ports, with Buffalo as the present easternmost terminal, will be touched upon first. Before doing so, however, it may be well to state that the subject matter of this paper deals with projects so vast that $1 000 000 is the lowest unit to be given consideration. If this is not clearly apprehended at

the outset, the large expenditures suggested may be set aside as extravagant and visionary. It is well, also, to state that where estimates of the cost of improvements recommended by the writer are given, they are not true detailed estimates, but are more in the nature of illuminated guesses. It is well, also, to state that the ton of freight wherever referred to in this paper means a ton of 2 000 lb. Miles are always statute miles. Wherever levels are mentioned, the reference is to height in feet above mean tide at New York in terms of the adjusted levels of 1903. This adjustment was made by the U. S. Coast and Geodetic Survey working in collaboration with the U. S. Lake Survey. Wherever the Lake Survey is referred to in this paper it means the Survey of the Northern and Northwestern Lakes, an organization under the Corps of Engineers, U. S. Army, with headquarters at Detroit, and with jurisdiction for surveys, chart-making and hydraulic and other investigations covering the whole Great Lakes System, extending westward and including the Lake of the Woods and eastward and southward to include Lake Champlain and connecting waterways.

The writer has mentioned casually the expenditure of something approaching $70 000 000 within the Great Lakes System to secure 25 and 26-ft. navigation. The United States Government has already expended in developing the right of way of the Great Lakes, including channels, canals, ship locks, breakwaters, harbors, light-houses, and aids to navigation, upward of $150 000 000. The new Welland Ship Canal, now under construction, to be completed perhaps by 1930, will cost fully $100 000 000. The engineers' report for the St. Lawrence development between a point a little above the Galops Rapids and Montreal is over $250 000 000. It is probable that any of these figures may vary in ultimate estimates by 10% or more, with a possibility always that the variation may be upward.

Navigation Values

To make understandable and justifiable proposed expenditures comparable with the cost of the Panama Canal, a quotation is made from the Presidential Address of the late Alfred Noble, Past-President, Am. Soc. C. E., for many years Dean of American engineers. This address,* entitled "The Development of the Commerce of the Great Lakes," was delivered before the Society in 1903.

"This wonderful development of a few leading articles of freight has resulted in cheaper transportation than known elsewhere, except on long ocean routes. The most reliable and complete data existing are obtained at the St. Mary's Falls Canals by the co-operation of the Governments of Canada and the United States. The average freight rate on all classes of freight during 1902 was 0.89 mill per ton-mile, the average haul being 827.4 miles. If the freight had been carried by rail the average rate could hardly have been less than 3 mills per ton-mile, and the average haul would have been about the same as by water. On this basis the saving in transportation by the water route during one year was nearly $63 000 000. This amount of saving on Lake Superior commerce alone, during a single year, is within $5 000 000 of the entire amount appropriated by the United States for all harbors and waterways on the Lakes above Niagara Falls from the formation of the Govern-

* *Transactions*, Am. Soc. C. E., Vol. L (1903), p. 327.

ment; if the commerce between Lake Michigan and Lake Erie be included, the annual saving greatly exceeds the amount thus appropriated. Indeed, the saving during one year on a single article, iron ore, would repay all the money expended up to this time on the waterways and harbors which it traverses on its way from mine to furnace. Viewed in this way, no great investment was ever made by a corporation or government with such a magnificent showing of profit. But a far broader view may be taken justly; this water route has not merely afforded a saving in expense of transportation, but has been creative of a large part of the wealth of the nation. Without it the development of our manufactures of iron and steel and other industries dependent on them or related to them, all constituting a great share of the national wealth, would have been retarded or impracticable; without it the prairies of the Northwest would have remained unproductive and unpeopled for a much longer time. With these broad considerations in view we may place to the credit of Lake transportation a sum perhaps hardly definable, but compared to which the largest above mentioned is a mere trifle."

In the year 1902, referred to by Mr. Noble, the commerce through the Soo Locks amounted to about 36 000 000 tons with a valuation of a little over $358 000 000. During the same year, the estimated freight passing through the Detroit River was over 44 000 000 tons with an estimated value of nearly $441 000 000. Fourteen years later, in 1916—a year when commerce was stimulated by the World War—the freight passing the Soo Locks was nearly 92 000 000 tons and that through the Detroit River exceeded 100 000 000 tons, with a valuation of nearly $1 070 000 000.

Applying the same rule for estimating the economic value of the right of way of the Great Lakes as used by Mr. Noble, the saving for the single year, 1916, was $175 000 000 for commerce passing the Soo Locks.

Water Values

It will appear later that the outflowing waters of the Great Lakes have incredibly large values. It has been estimated that the diversion of 10 000 cu. ft. per sec. in the Drainage Canal is worth $8 000 000 a year to Chicago. The total ultimate usable power in the Niagara River is nearly 3 000 000 e.h.p. Should the installations for the use of this power cost $100 per e.h.p.—a low figure—the investment in that river alone will be $300 000 000. The present capitalization of the Niagara Falls Power Company is more than $75 000 000. On the St. Lawrence River upward of 4 000 000 e.h.p. will ultimately be developed. This will warrant an expenditure of more than $400 000 000.

Justification

After these vast sums are fully comprehended and digested, the justification of the expenditure of considerable sums in securing the highest carrying capacity of the vessels of the Great Lakes, through better and deeper channels —and, hence, cheaper freight rates—becomes apparent; and the advisability of utilizing for water-power betterment the vast storage reservoirs of Lake Superior and Lakes Michigan-Huron becomes obvious.

A great temptation exists for the writer to go into the historical phase of the development of the commerce of the Great Lakes. Instead, reference is again made to the Presidential Address of the late Mr. Noble previously

noted. The beginnings of the navigation of the Great Lakes reach back to a period of exploration, adventure and romance, perhaps more interesting than the cold recital of statistical facts and the cold development of engineering projects to add to the economic value of the right of way of the Great Lakes. This paper deals with the present and with the future and utilizes the past only to make the future understandable.

During the 1923 season of navigation—which may be regarded normally as having a duration of a little less than eight months, from April 15 to December 15—the freight passing the locks at Sault Ste. Marie amounted to over 91 000 000 tons, with a value exceeding $1 000 000 000. The total freight paid was nearly $81 000 000, which included loading and unloading, except in the case of coal. The average distance carried was roundly 800 miles. The average freight charge per ton for this distance was 88 cents, which indicates an average cost of 1.1 mills per ton-mile. It is a fair assumption that this freight if carried by rail would have cost over four times as much.

Deferred Maintenance

This land-locked waterway—the right of way of the Great Lakes—should be maintained in the same excellent condition as the right of way of a great railway, such as the Pennsylvania System or the New York Central Lines; but the fact is that the levels of the Great Lakes, on which the drafts of vessels depend for their loading capacity, have been permitted to lower, following the caprice of natural rainfall conditions; and have been artificially lowered by diversions for sanitation at Chicago, by diversions for power and navigation purposes in the Welland Canal and in the Niagara River, and have been lowered by the additional outflow capacity of the rivers themselves, created by the deepening of river reaches for ship channels. The depth betterment, for 20 and 21-ft. channels between Buffalo, Chicago, and Sault Ste. Marie, has been secured by excavating the lake and river bottoms below the level of extreme low water rather than by the elimination of extreme low water through the maintenance of the surface levels of the lakes.

The first step toward the St. Lawrence Waterway to the Sea is to bring up the levels of the lakes and the inter-lake rivers between the foot of Lake Erie, the southernmost extremity of Lake Michigan, and the westernmost extremity of Lake Superior. The maintenance of the surface levels of Lake Ontario is an integral part of the St. Lawrence River project and will be discussed in the general review of that project as part of the St. Lawrence Waterway to the Sea.

During the present season of navigation (1924), the St. Marys River, below the foot of the Soo Locks, and Lakes Michigan-Huron have been at their lowest recorded stage in a period of 65 years. The reason for this low stage involves the various diversions already mentioned, but is caused predominantly by the temporary absence of abundant rainfall in the Great Lakes System and by the absence of regulating works at the head of the St. Clair

River, where the lake waters outflow toward Lake St. Clair, the Detroit River and Lake Erie. (See Plate IV.)

It must be understood that the dearth of precipitation shown by the low levels of Lakes Michigan-Huron and Erie is not confined to this drainage basin but is widespread over the United States. California is having a water famine without precedent. The Mississippi River at Minneapolis in January, 1924, showed its lowest recorded flow. Most frequently, precipitation meagerness is somewhat localized. The drainage basin of Lake Superior may have an abundant water supply at a time when the Lake Erie Basin is deficient. It will appear later that the diversity factor applies to the basins of the Great Lakes and that advantage of this factor may be secured only by two operations: First, by conserving the flood waters in the upper reservoirs; and, second, by arranging for the transfer of these stored waters without time loss to the lake where navigation or water power requires additional supply. This obviously is the function of regulating works which will be discussed in detail in subsequent paragraphs.

Value of Draft

It is desirable to apprehend clearly what draft means in the carrying capacity of the freighters of the Great Lakes. The largest of these freighters exceeds 600 ft. in length. The tonnage of freight for a vessel drawing 20 ft. of water is carried by a displacement of perhaps 10 ft., the weight of the vessel and its non-productive cargo requiring the displacement of the other 10 ft. This means for this type of vessel that a loss of 1 ft. in draft involves a loss of upward of 1 000 tons of freight.

The elevation of Lakes Michigan-Huron for the season of navigation of 1924 is 579.3. The mean stage of Lakes Michigan-Huron during the seasons of navigation over a period of 65 years was 581.5. Based on the mean elevation for a period of 65 years, this indicates that in 1924 Lakes Michigan-Huron are deficient in navigable depth 2.2 ft., which means a loss of 2 200 tons in carrying capacity for each large lake freighter on each trip, with little change in the cost of operation. It is obvious that this must mean increased freight rates.

Expressing the loss of draft in inches as a matter of convenience, the season of navigation shows a deficiency in draft of 26 in. Chicago is chargeable with 5 in., through its diversion to the present time of about 9 000 cu. ft. per sec. Diversions in Lake Erie for purposes of navigation and water power are chargeable with perhaps a back-water reflection of 1½ in. Enlargements in the channels of the St. Clair and Detroit Rivers are responsible for perhaps 3½ in. The remaining loss of draft of 16 in. is chargeable to lack of normal precipitation and the absence of regulating works at the head of the St. Clair River.

The economic value of 1 in. in draft has been estimated as $500 000 per year. While this figure may be a little on the large side, it will be used in this paper. It must be understood that the large types of freighters on the Great Lakes are capable of loading to 24 ft., that they load to the last

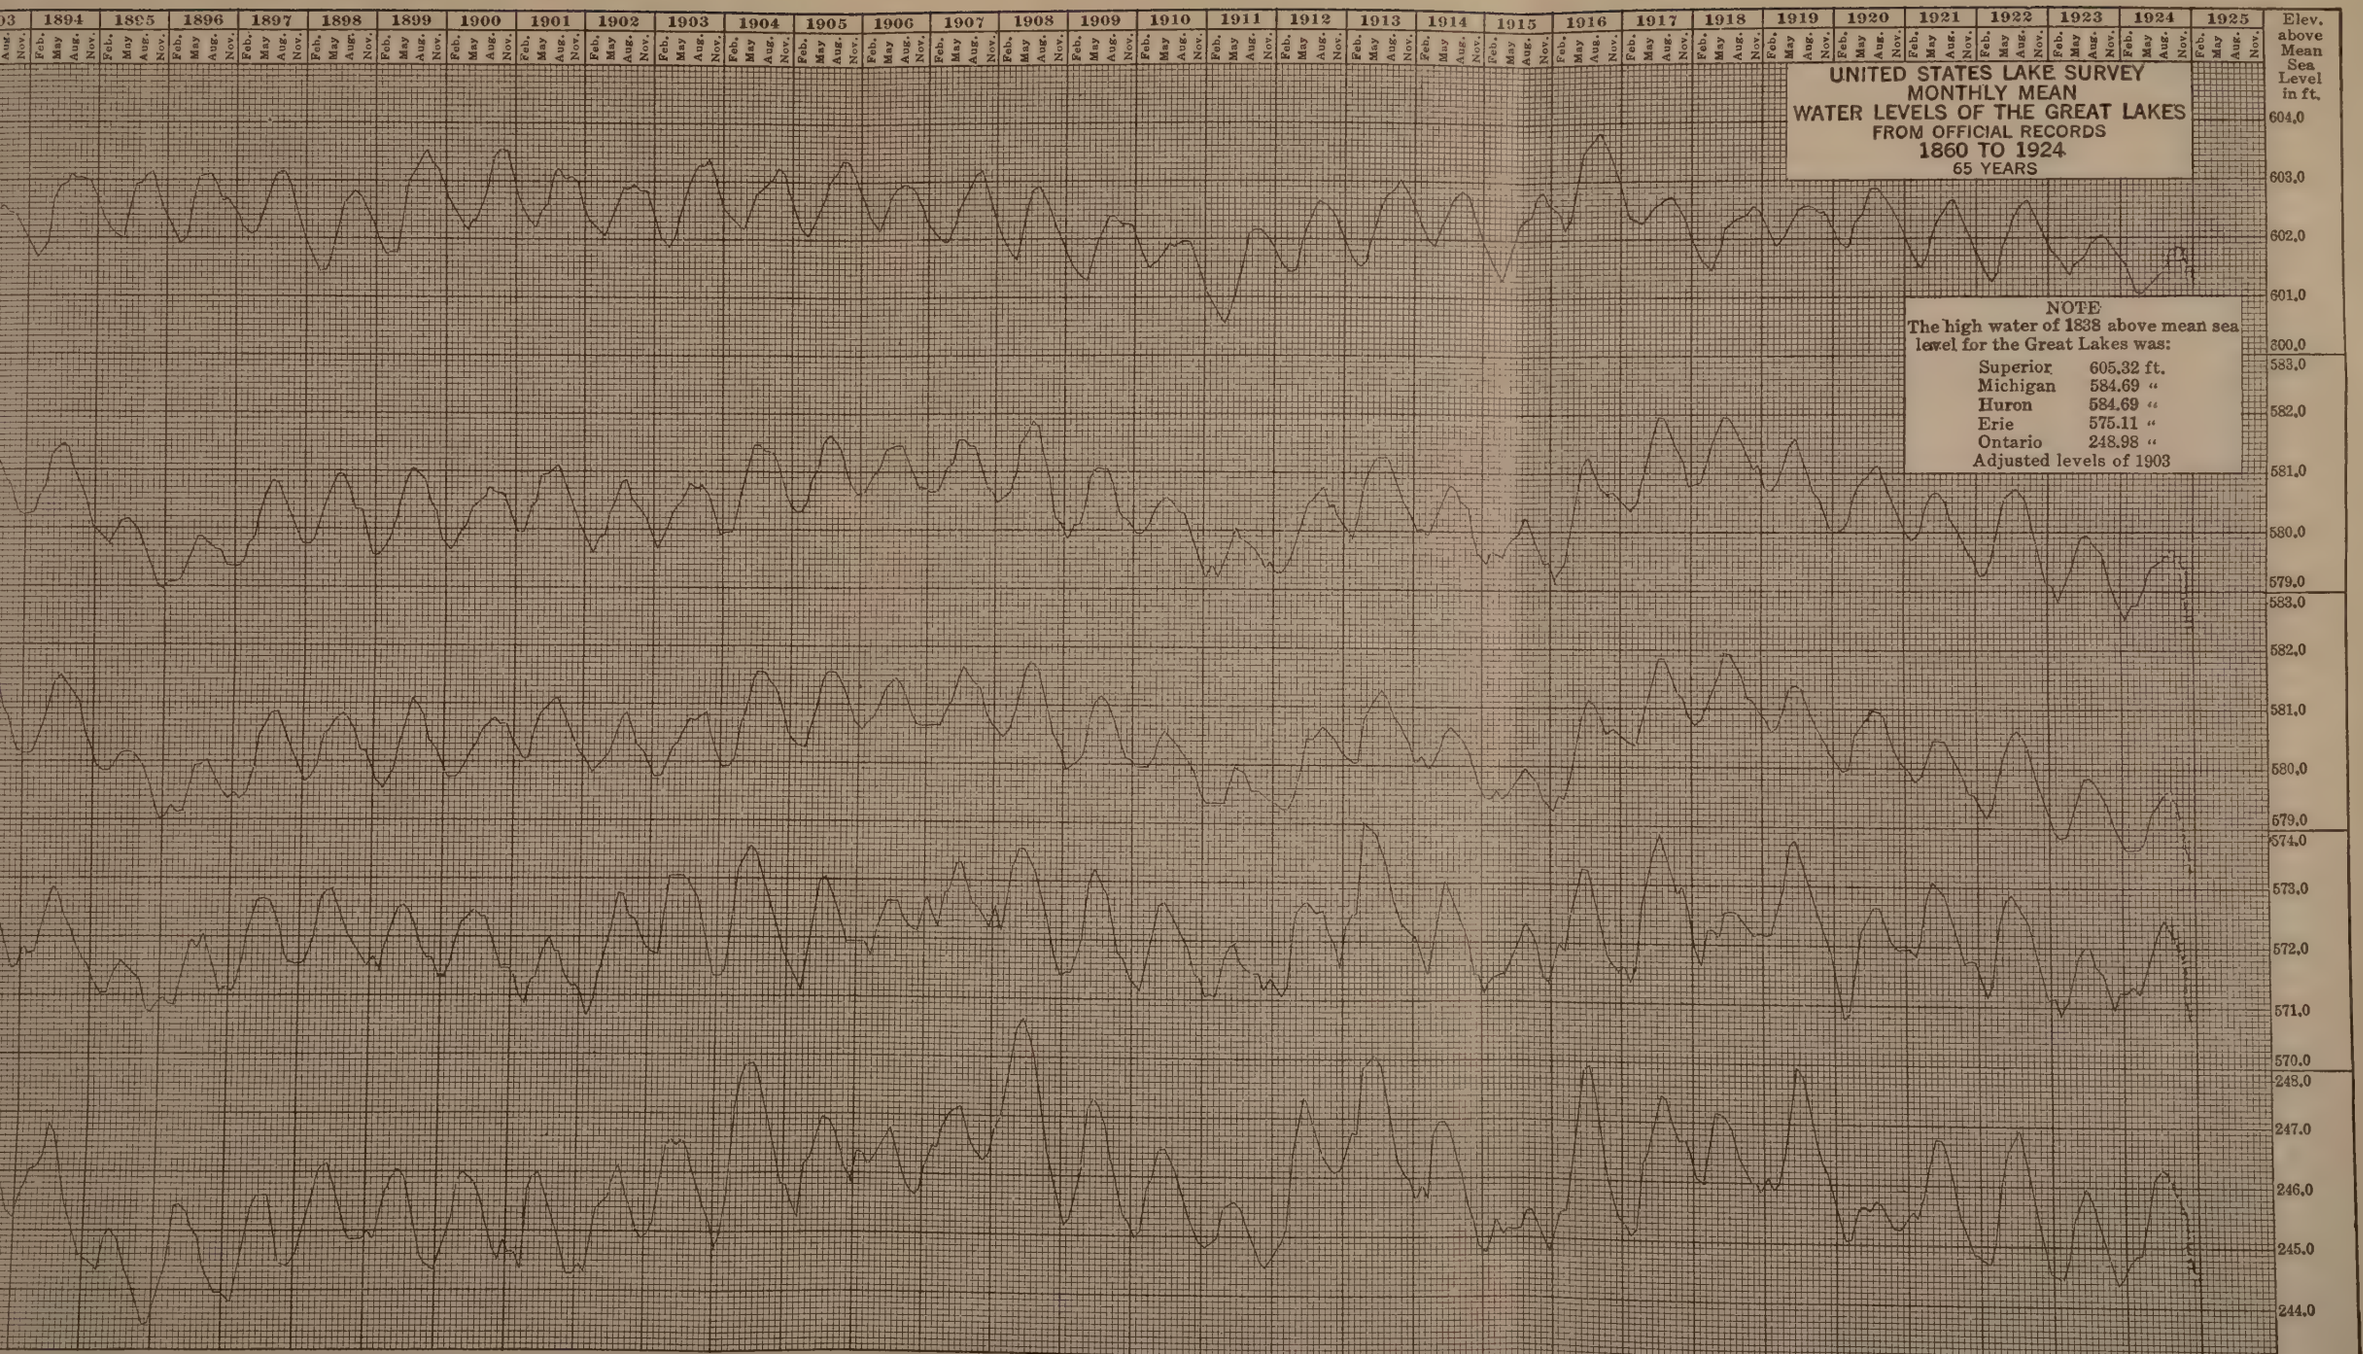
SHENEHON ON
THE ST. LAWRENCE WATERWAY
TO THE SEA.



inch available in the channels they are to traverse, and that the loading is directed by telegraphic advice.

Assuming the correctness of this figure of $500 000 for a 1-in. draft, the loss for the 1924 season of navigation, based on 26 in. of deficiency, is $13 000 000. With reasonable reductions for a conservative estimate, it is certain that this loss under ordinary trade conditions would mean $10 000 000 for the navigable season of 1924. It happens, however, that depressed conditions have resulted in smaller shipments than usual and that vessels are available to carry the tonnage to be moved on lesser drafts. For this reason, the real economic loss on the Great Lakes for 1924 is somewhat less than the figure given.

During the season of 1923, the elevation of Lakes Michigan-Huron was 579.7. Based on a mean water-surface elevation for these lakes of 581.5, the deficient draft for this season of heavy shipments was 22 in., with a loss of upward of $10 000 000 for the year.

Assuming that these estimates of economic loss coming from deficient drafts in the channels of the St. Marys River, Lakes Michigan-Huron, and in Lake Erie, are anywhere nearly correct, it appears that the maintenance of lake levels by regulating works at the head of the St. Clair River, installed at the cost of perhaps $10 000 000, and regulating works at the head of the Niagara River at a cost of perhaps $10 000 000, is a most obvious economic necessity; and if it appears that some part of the cost of these works may be properly charged to water-power betterment at Niagara Falls and in the St. Lawrence River, the economic desirability is still further emphasized.

Low Levels Anticipated

The degraded levels of Lakes Michigan-Huron in the years 1923 and 1924, which have been cited, were a reasonable expectancy based on the water-supply conditions of the Great Lakes over a period of 65 years beginning in 1860. In the year 1895, the level of Lakes Michigan-Huron during the season of navigation was only 1 in. higher than in 1923; and in the year 1896, the level of these lakes was the same as in the season of 1923. These low levels of more than a quarter of a century ago preceded the deeper excavations in the St. Clair and Detroit Rivers, preceded the opening of the Chicago Drainage Canal and preceded any large diversions for water-power purposes in the Welland Canal and in the Niagara River.

Desirable Elevation

During the seasons of navigation for a 5-year period, 1883 to 1887, inclusive, the elevation of Lakes Michigan-Huron was 582.8. The writer suggests the regulation of these lakes during the season of navigation at the same elevation, 582.8, with a possible pull-down of 1 ft. of storage for water-power betterment in the Niagara and St. Lawrence Rivers in periods of meager precipitation.

Assuming the normal regulated stage of Lakes Michigan-Huron as 582.8 during the season of navigation, the deficient drafts during the season of

1923 amounted to 37 in. and during the season of navigation of 1924 to 42 in. These figures may be lessened to 25 and 30 in., based on the lower regulated level of these lakes after an occasional pull-down of 1 ft. for the use of the accumulated storage.

Conditions at Soo Locks

The effect of these low levels, and particularly that of 1924, in the lower approach to the ship locks at Sault Ste. Marie, should be noted. The water-surface elevation in the river just below the locks in a period of small river flow, such as that at the present time, is about 9 in. above the water-surface elevation of Lakes Michigan-Huron. In times of ample flow, the water level at the lower entrance to the locks may be 1 ft. or 1½ ft., under present conditions, above the level of these lakes. With the present degraded mean levels for the season of navigation of 1924, the permissible draft of vessels passing through the Poe Lock is about 17.5 ft. and the draft of vessels passing the Canadian Lock is limited to 17.7 ft. These locks were built in connection with the project in which the 20 and 21-ft. drafts provided for, were based on mean lake levels rather than on extreme low lake levels. It is for this reason, and because the level of the St. Marys River at the lower approach to the locks has been further degraded by excavating deeper channels throughout the lower river, that these two ship locks are of no value this year (1924) for other than light-draft vessels. Vessels loading to 18 or 19 ft. must pass through the two new American locks—the Davis Lock and the Sabin Lock. It is obvious that bringing Lakes Michigan-Huron levels up 3 ft. or more by regulation, will make available again these two ship locks for 20-ft. navigation.

During the present season, the conditions in St. Marys River and in Lakes Michigan-Huron control drafts. During other seasons, the drafts of vessels have been limited by Lake Erie channels, which will be discussed later in connection with regulation works at the head of the Niagara River.

The Port of Duluth

The zero point for the St. Lawrence Waterway to the Sea is at Duluth, at the westernmost extremity of Lake Superior, 950 miles westward and 410 miles northward from the Port of New York and 1 420 miles eastward from Seattle. (See Plate III.) By a somewhat remarkable natural coincidence the St. Louis River enters Lake Superior at this westernmost point and a delta formation of alluvial material forms a natural breakwater 8 miles in length, protecting the estuary of the river from storms. This spit or breakwater is pierced by harbor entrances in two places, one toward its northwestern extremity leading to the inner basin of the Harbor of Duluth. Southeasterly from this entrance about 6¼ miles is an entry first, through artificial breakwaters to an outer harbor, and, then, through a passage 400 ft. wide, to the inner basin of Superior Harbor. As the St. Louis River forms the boundary line between Minnesota and Wisconsin, the twin harbors connected by a vessel channel behind the breakwater, are interstate. Aside from the 4-mile channel connecting the two basins, there are more than 13 miles of channels leading to the various docks of the two harbors.

The harbor entrances are already deep enough for 25-ft. navigation. For the most part, the various channels and the basins of the harbor will require dredging to a depth of perhaps 3 ft. to provide for 25-ft. navigation, with higher regulated levels of Lake Superior. The material to be excavated in deepening the harbor channels is largely silt and sand, underlaid by boulder clay. All the material may be handled by suction dredges, using cutters in the clay, at a probable cost not exceeding 20 cents per cu. yd.

The Government has already spent—or is completing the expenditure of—a little over $8 500 000, including maintenance. The cost of maintenance for 1925 is estimated at $52 500. Private companies and the City of Duluth have expended about $200 000 in breakwaters and trunk-line channels. An expenditure of about $1 000 000 will provide 25 and 26-ft. depths in the twin harbors.

The following statements are briefed from the 1923 reports of E. H. Marks, Major, Corps of Engineers, U. S. A., Assoc. M. Am. Soc. C. E., in charge of the work:

The entire protected harbor area aggregates 19 sq. miles, with about 49 lin. miles of frontage, only 6 miles of which are occupied by wharves. Nine iron ore docks, aggregating 8 720 ft. in length, have a total combined storage capacity of 1 080 000 tons; 24 coal docks have an aggregate storage capacity of 11 305 000 tons; 26 elevators have a total storage capacity of 36 325 000 bushels; a modern cement elevator has a storage capacity for 114 000 bbl. of cement, with an unloading capacity of 1 000 bbl. per hour. Most of these docks and elevators are up to date in facilities for the quick handling of ore, coal, and grain, and are probably not surpassed by those of any other port. Practically all the wharves, docks, and elevators are privately owned. The facilities for handling package freight, lumber and general merchandise were primitive up to 1924, when a new terminal plant, privately owned, but open to the public, was made available. Three shipbuilding yards and forty-three wharves handle freight other than iron ore, coal, and grain. Ten railroads, either direct or through affiliated lines, connect with the water terminals.

Major Marks sums up the value of improvements in the Duluth and Superior Harbor as follows:

"The effect of the work done under the existing and previous projects has been to facilitate navigation by means of deeper and wider channels, with commodious anchorages and turning basins and safe entrances to the harbor, as well as to give refuge to vessels seeking shelter from storms. Through these improvements, which permit the use of larger vessels, freight rates have been materially reduced."

Inter-lake navigation, based on records for the past 20 years, begins normally on April 20, and terminates on December 14, showing a navigation season of 239 days for Duluth.

Duluth Commerce

In 1923, the commerce of the Duluth-Superior Port shows over 59 000 000 tons, with a valuation of nearly $450 000 000. Of this commerce, the outbound tonnage amounted to a little over 45 000 000, while the inbound com-

merce amounted to a little over 14 000 000 tons. This shows an outbound balance of roundly 31 000 000 tons, indicating that many upbound vessels travel light or with water ballast. Iron ore, with a value of $4.32 per ton, constitutes 58% of the outbound valuation and 94% of the outbound tonnage. Wheat, high in value, but low in weight, constitutes 13% in value and 7½% in tonnage. Shipments of animals and animal products show a valuation of $14 500 000; vegetable and food products, including wheat, $17 500 000; wood and wood products, $800 000; unclassified freight, $3 900 000; and copper nearly $8 000 000. The dominant inbound cargo is coal, 12 700 000 tons in 1923, with a value of $72 245 000. The total inbound commerce has a valuation of nearly $132 000 000.

Canadian Ports

About 200 miles northeast of Duluth are the harbors of Port Arthur and Fort William in Thunder Bay. These are the terminals for the railways that tap the fields of Canada's great western granary and bring wood products as well. This harbor is landlocked against Lake Superior seas by Isle Royal lying across the entrance to Thunder Bay, by Pie Island lying midway of the entrance, and by Thunder Cape. This westernmost Canadian port, with its capacious roadstead, has unlimited capacity and ample drafts for ocean vessels.

Type of Vessel

The largest portion of the commerce of these ports is carried in a typical vessel of a length of 600 ft., with a beam of 60 ft., and built for drafts of 24 ft. The engine is carried aft, and the freight hold extends nearly the full length of the vessel. The deck is largely made up of hatches for rapid loading and unloading. The economic speed of travel in open water is about 11 miles per hour. The engine has about 3 000 i.h.p.

Duluth to the Soo

One of these freighters, carrying 10 000 tons of cargo on a 20-ft. draft, leaving Duluth, traverses the deep waterway of Lake Superior—1 000 ft. deep in places—and reaches the ship locks at Sault Ste. Marie, 394 miles away, in about 36 hours. It requires an hour for the freighter to pass the ship locks, descending 20 ft. to the level of St. Marys River below the rapids.

The Sault de Sainte Marie

Fig. 2 is an airplane view of the layout of the various works at Sault Ste. Marie, and Fig. 4 explains the photograph and gives much desirable information.

It should be noted that regulating works, consisting of a battery of Stoney gates, control the outflow and levels of Lake Superior. These regulating works and St. Marys Falls Canal are about 14 miles down stream from the foot of Lake Superior. Upper St. Marys River is for the most part 1 mile or more in width and runs deep and still. The descent from Lake Superior

level to the level of the river at the regulating works varies somewhat with the volume of flow, but may be taken as 0.3 ft.

The writer suggests the regulation of Lake Superior at Elevation 603 as a mean during the season of navigation, with a pull-down of 1 ft. for storage water in case of navigation need in the lower lakes or in the water powers of the Niagara and St. Lawrence Rivers. Based on these regulated lake surfaces, about 3 miles of dredging—deepening 22-ft. channels to 25-ft. channels—would be required in the upper river.

Ship Locks

Four ship locks on the American side of the river and one ship lock on the Canadian side are in operation. Down-bound vessels approaching these locks pass through about a mile of canal with ample mooring space. The Canadian Lock, completed in 1895, is 900 ft. long and 60 ft. wide, and is intended for 22-ft. drafts, but during the mid-season of 1924, due to depressed river pool conditions, low lake levels, and small volume of river outflow, the draft over the limiting barrier at the lower entrance of the locks was only about 17.7 ft. On the American side, the Weitzel Lock, 515 ft. long and 80 ft. wide, narrowing at the gates to 60 ft., was completed in 1881 and was intended for 14-ft. navigation, but has only about 12 ft. over the lower breast-wall. The Poe Lock is 800 ft. long and 100 ft. wide, built for 22-ft. drafts, but in 1924 had about 17.5 ft. in the lower entrance. The writer had a small part in the building of this ship lock. It was intended as a 4-vessel lock, each vessel having a length of 400 ft. and a beam of 50 ft. It was completed in 1896 and in the interval of less than 30 years, it has become a single-vessel lock for a typical lake freighter when traveling light. The Davis Lock was completed in 1914, has a 1 350-ft. length and an 80-ft. width, with 24 ft. of water on the lower breast-wall despite lower-pool depression, small outflow, and low lake levels. The Sabin Lock (Fig. 3), of the same dimensions as the Davis Lock, was opened to traffic in September, 1919. It is in gracious appreciation that this lock bears the name of Mr. Louis C. Sabin, in local charge of construction and operation of the works in St. Marys River since 1906. The other American locks bear the names of officers of the Corps of Engineers, U. S. Army. (See Fig. 2.)

The Poe Lock had a pre-war cost of $3 000 000 and the Sabin Lock, built in 1913 to 1919, cost $2 500 000. The total cost of improvements in St. Marys River to July, 1923, aside from the practically obsolete Weitzel Lock, amounts to $30 000 000. The cost of operation of the locks and canals on the American side was $141 200 in 1923 and the maintenance cost was, roundly, $105 000. The total cost of operation and maintenance during the past 10 years has amounted to 2¾ mills for each ton of cargo passing the ship locks.

It should be noted that the necessary time spent by vessels in traversing 1.6 miles of canal and passing the ship locks, averages roundly 1½ hours. This means that practically 1 hour is necessarily spent in the lockage. This time is in part utilized in taking on supplies.

With regulated Lake Superior and Lakes Michigan-Huron levels, the Davis and the Sabin Locks will become available for 25 and 26-ft. navigation,

although this will probably involve a lowering by perhaps 1 ft. of the breast-wall and the miter-sills of the upper approach. It should be accentuated that increased drafts and larger cargoes mean fewer vessels and, therefore, fewer necessary locks. The Canadian Lock and the Poe Lock will still normally remain available for 20-ft. navigation, while the two new American locks will care for deep-draft vessels. This link in the St. Lawrence Waterway from Duluth to the Soo is, therefore, substantially existent.

St. Marys Falls Canal Statistics

An average of 92 vessels per day passed the five locks during the season of 1923, of which 55 passed through the Davis and Sabin Locks and 17 through the Canadian Lock.

In 1923, the total freight carried was 91 380 000 tons. This freight had a valuation of $1 026 045 064, and the freight charges amounted to $80 843 000. The east-bound freight passing through the Soo Locks was 71 236 000 tons, and the west-bound, 20 144 000 tons. The valuation of 774 registered vessels using the locks was $254 630 000. The average distance which freight was carried was 801.3 miles and the average cost per ton for freight transportation was 88 cents, showing a cost per ton-mile of 1.1 mills. In 1923, American vessels carried 92.7% of the total freight, and Canadian vessels, 7.3 per cent. The total valuation of registered Canadian vessels is given as $29 128 350, which is 11.4% of the total valuation of all registered vessels passing the Soo Locks.

The American Canal was operated 231 days during the somewhat shorter than usual season of 1923. The normal navigation season during the past 20 years has been from April 18 to December 19, or 246 days. In 1923, over 98% of the freight was carried during May to November, inclusive, the month of July showing the largest tonnage.

The statistical report of lake commerce passing through the canals at Sault Ste. Marie, Mich., and Ontario, during the season of 1923, with a supplementary report of commerce passing through the Detroit River, prepared under the direction of E. M. Markham, Colonel, Corps of Engineers, U. S. A., with headquarters at Detroit, is a most interesting informative document. Students of water transportation need this pamphlet.

In 1922, of the total of 600 vessels, 158 carried cargoes of 10 000 to 14 000 tons. In 1923, with lower lake levels, only 110 vessels carried cargoes of these sizes.

The dominant east-bound tonnage for American vessels is iron ore and for Canadian vessels flour, wheat, and other grain. The dominant west-bound cargo for American vessels is coal, 10 tons of soft coal to 1 ton of hard coal. The dominant west-bound cargo of Canadian vessels is general merchandise.

The following tabulation shows the tonnage and percentage of tonnage of the total east-bound traffic for 1923 through the Soo Canals:

Iron ore	59 200 000 tons	83.2%
Grain	10 000 000 "	14.0%
Flour	1 500 000 "	2.1%
Miscellaneous	0 500 000 "	0.7%

For west-bound cargoes, coal, 18 400 000 tons, constitutes 87% of the tonnage.

Perhaps the valuation is a better criterion of the use of a waterway than the number of tons carried. Of the total valuation of $1 026 045 064, the valuations of various classes of cargo are, as follows:

Lumber	0.69%
Flour, wheat, and other grain	41.93%
Copper	1.65%
Iron ore, pig iron, and manufactured iron and steel	30.51%
Coal, soft and hard	9.98%
Miscellaneous merchandise	15.24%

It should be noted that the valuation of all freight carried, outside of iron ore, is $720 356 808.

The freight rates for various commodities in 1923 were as follows, reduced to cost per ton, including loading and unloading except in the case of coal:

Lumber	$2.75
Flour	3.50
Wheat	1.27
Other grains	1.52
Copper	5.00
Iron ore	0.83
Pig iron	2.85
Manufactured iron and steel	2.50
Coal	0.45*
Salt	1.25
Oil	1.25
Stone	0.50
General merchandise	5.00

These freight charges bear some relation to the value of the commodity itself. Lumber has a value of $18.65 per ton; flour, $62.50; wheat, $35.30; grain other than wheat, $29.60; copper, $281.00; iron ore, $5.15; pig iron, $30.85; manufactured iron and steel, $85.00; coal, soft, $5.00; coal, hard, $11.20; salt, $8.90; oil, $41.00; stone, $1.10; and general merchandise, $225.00.

It is obvious also that the space occupied by freight of a given class, as well as the difficulties of loading and unloading, enter into the freight rates charged. Taking 100 cu. ft. as the measure of the registered ton of vessel capacity, 1 ton of wheat occupies 37⅓ cu. ft. of space; 1 ton of lumber occupies 40 cu. ft.; and 1 ton of general merchandise is understood to occupy 100 cu. ft., which figure, however, has wide variations. The freight passing the Soo Canal in 1923 shows 1.43 tons of freight carried for each registered ton of vessel capacity. This means that the average ton occupied 70 cu. ft. of space.

These statistical figures are tedious and need to be read only by those who wish to analyze the water-transportation problem in its bearing on the land-locked commerce of the United States and the possibilities of emergence of this commerce into the salt seas. The big problem aside from carrying capacity, appears to be that of increasing the load factor of vessels of the Great Lakes

* Does not include loading and unloading.

by the stimulation of up-bound cargoes and by 12-month operation. Coal shows a marked upward volume of tonnage, the coal carried in 1900 being less than 4 500 000 tons, while that carried in 1923 was more than 18 400 000 tons. Grain cargoes are also increasing, showing for a period about 1900, 73 000 000 bushels and for 1923, 370 000 000 bushels. Lumber, on the other hand, shows a declining tonnage. The growth in the transportation of general merchandise is very small.

Forecast

For the coming decades it is probable that the shipments of high-grade, commercial, hematite iron ore will decline. This decline will be replaced, in part at least, by the shipment of ores of lower grade which will be concentrated before shipment by the removal of some non-metallic elements. The shipment of coal will increase largely with each decade, tending more nearly to equalize up-bound and down-bound cargoes. The greater carrying capacity of vessels which will come with deeper drafts, the near-balance of up-bound and down-bound cargoes, and the final utilization of some vessels now limited to an 8-month year for ocean service during the four ice months, will all tend to the further reduction of freight rates.

It is interesting to note the economic value of the present commerce of the Great Lakes, excluding iron ore and coal. Aside from these commodities, the 1923 shipments on the Great Lakes aggregated, for the Soo Locks, 13 627 404 tons, and the freight paid was $23 398 840. These shipments, assuming an average travel of 800 miles, represent a ton-mile rate of 2.14 mills. A normal rail rate per ton-mile is 11 mills. The saving by this part of the transportation on the Great Lakes over rail on these commodities alone represents an excess of more than $90 000 000 for 1923.

Assuming the elimination of iron ore alone, and considering coal and all other commodities, and taking a rate of $1.00 per ton on up-bound coal, the aggregate carried through the Soo Locks in 1923 is 32 022 715 tons and the freight charged would be $41 694 150. The average rate per ton-mile then becomes 1.63 mills. This is less than one-sixth the normal rail rate. It should be understood that if it were not for the cheap freight rates on the Great Lakes, much of the iron ore of Minnesota might lie unused in the ground, the ores coming from other sources; and coal might come by rail from Illinois and Kentucky instead of from the Pennsylvania mines. About 80% of the iron used in the United States comes from the mines tributary to Lake Superior. It is probable that ultimately iron ore will be exported from Minnesota.

The Soo to Port Huron

The 600-ft. freighter coming down Lake Superior from Duluth and reaching the Soo Locks 36 hours later has spent 1½ hours in passing through the locks and canals, including the examination of statistics. The descent in the locks is about 20 ft. under normal conditions. Leaving Sault Ste. Marie, down-bound, the vessel course follows for 2 miles the partly improved river with a

width of ¾ mile, then for a distance of 5 miles in a dredge cut through Little Rapids into Hay Lake. This lake is about 1 mile wide and, for 4 miles, has depths requiring little or no dredging to secure 25-ft. drafts. The channel splits about midway of Hay Lake, down-bound vessels taking the West Neebish Channel and up-bound the Middle Neebish Channel for a distance of 14 miles, when the course leads into Mud Lake and the estuary of St. Marys River—upward of 2 miles wide. From here to Point Detour is 25 miles of clear sailing in a channel the greater part of which is 1 mile or more in width. At Point Detour, vessel courses radiate toward Lake Michigan and Lake Huron ports. Vessels bound for Chicago, work to the westerly in Lake Huron and through the Straits of Mackinaw to the foot of Lake Michigan, 423 miles away. The down-bound 600-ft. freighter passes down Lake Huron with depths as great as 400 ft., reaching Port Huron, Mich., at the head of the St. Clair River, in 216 miles of travel and 20 hours after leaving Point Detour. This is 62 hours from Duluth.

Suggested Works

At the foot of Lake Huron—at the head of the St. Clair River—the writer suggests regulating works to maintain lake levels and create storage. Such regulation means that the elevation of Lake Huron will be normally 1 to 2 ft. or more higher than the water in the head-of-the-river pool opposite Fort Gratiot Lighthouse. The elevation of the water at Fort Gratiot primarily determines the outflow through the St. Clair River; and conversely the surface elevation or stage of Lakes Michigan-Huron is determined by the abundance or meagerness of the water supplied to these lakes. It is purposed to curtail the natural prodigal outflow from the Michigan-Huron Reservoir in times of opulent water supply and during the winter so as to store the water against periods of meager water supply; and it is proposed to release reservoired water, when Lakes Erie and Ontario need navigational uplift and when hydro-electric plants in the Niagara and St. Lawrence Rivers require volume maintenance. Regulating works above the head of the St. Clair River will co-ordinately require navigational passes to permit up-bound vessels to ascend from the head-of-the-river pool level to the lake level. (See Fig. 5.) The 600-footer, down bound, will enter the 600-ft. wide pass and traverse without delay the three expansion basins proposed. Up-bound vessels will encounter no inconvenience or delay. No ship locks will be required.

Port Huron to Detroit

At present, the down-bound 600-ft. freighter passes directly into the gorge of the St. Clair River at Port Huron, 800 ft. wide, 50 ft. deep and flowing with a velocity of 5 miles per hour. Just below this rapid descent of the upper river is 1 mile of duplicate channels. For the greater part of 27 miles the river is more than ½ mile wide, with water varying from 25 to 50 ft. deep. The current, except at Port Huron, is leisurely. Just below Algonac, Mich., 28 miles below Port Huron, the river enters a delta formation radiating into a series of channels somewhat similar to those at the mouth of the

FIG. 5.

Mississippi. In making an artificial channel the material to be excavated is alluvial. For a distance of 11 miles, the channel is 500 to 1 000 ft. in width, with some curvature. Ultimate deep channels will involve rectification as well as deepening of some portions of this reach. The 600-ft. freighter passes into Lake St. Clair through the St. Clair Flats Canal with duplicate channels. Lake St. Clair is practically an enlargement of the rivers between the foot of Lake Huron and the head of Lake Erie. The bottom is largely of fine sand, with some clay. The vessel track across Lake St. Clair is 15 miles long and has a width of 600 to 800 ft., much of which has been artificially deepened by the stirring up of the bottom by the propeller wheels of the many passing vessels. Although the natural depth of at least 10 miles of Lake St. Clair was about 21 ft., the channel dredged by vessel travel has a depth of about 24 ft. This deepening of channels by propellers means simply the roiling of the water, with a portion of the material thrown into suspension depositing outside the channel. This condition is possibly pertinent in the consideration of the maintenance of Lake St. Louis, Lake St. Francis, and Lake St. Peter in the St. Lawrence River where the alluvial material is somewhat similar. Lake St. Clair is normally 5.5 ft. below the level of Lake Huron and 3.1 ft. above the level of Lake Erie.

Detroit

The center of the Port of Detroit is 6.5 miles below the head of the Detroit River and the foot of Lake St. Clair. The river at this point is ½ mile wide, with depths from 30 to 45 ft. and a current of perhaps 2 miles per hour. The harbor front extends practically from the head of the river down for a distance of 13 miles. On the north bank of the river is the Canadian City of Windsor. Additional harbor frontage is given by the improvement of the Rouge River—5 miles down from the center of Detroit—where Mr. Henry Ford has extensive works. The Port of Detroit is 724 miles from Duluth, involving 66 hours of vessel travel. The name, Detroit, means a strait, and this river, 27 miles in length, connecting Lake St. Clair with Lake Erie, varies in elevation with Lake Erie heights which are reflected by back-water into Lake St. Clair.

Detroit to Buffalo

Southward, for a distance of 14 miles below the center of the Port of Detroit, the river is capacious, requiring little or no dredging to develop it. Then the river shallows, showing estuary conditions. A little lower down, the channel splits, down-bound vessels following the Livingstone Cut, and up-bound vessels taking the old improved Canadian Channel. This reach of the river requiring improvement has a length to Bar Point, Ont., of 6.5 miles; and for 3 miles more through the delta formation of Lake Erie additional dredging will be required.

From Bar Point to the Port of Buffalo is 240 miles of clear sailing in open Lake Erie. This lake is the shallowest of all the Great Lakes, having depths for the most part of 100 ft. or less. The west end of the lake shows depths of 25 to 35 ft. for a distance of 30 miles. On account of the tendency of Lake Erie to tilt up in times of severe storms, channels have been dredged to greater

depths than in the other more stable lakes. It will be shown subsequently that the betterment of Erie levels is involved in this storm-tilting of the lake.

The Port of Buffalo is 985 miles and 90 hours travel from Duluth. The entrance to the Welland Canal at Port Colborne, Ont., is 10 miles less. These ports represent the present eastern limit of deep-draft navigation.

The waters of Lake Erie discharge through the Niagara River with its head at Buffalo. The Board of Engineers for Rivers and Harbors of the Corps of Engineers, U. S. Army, recommended in 1920, immediate construction of regulating works at the head of the Niagara River to maintain Lake Erie levels. The writer will discuss works at this point in connection with the control of all the outflow rivers of the Great Lakes for the dual purposes of the maintenance of the best navigable depths and at the same time the creation of storage for water power in the Niagara and St. Lawrence Rivers.

Outlets to the Sea

The navigable waterway of the Great Lakes with its deep penetration of the continent (see Plate III), and its large commerce cannot remain always a land-locked interior basin without adequate connection with the salt seas. For a century the desirability of this connection has been obvious and considerable steps toward its achievement have already been made. The Erie Canal was begun in George Washington's day and about the same time the Canadians were building waterways entering the Great Lakes System by the way of the St. Lawrence River and Lake Ontario and then over the Niagara Escarpment through the Welland Canal to Lake Erie. In the summer of 1924, the centenary of the beginnings of the Welland Canal was celebrated. The present Welland Canal with 14-ft. drafts and lock chambers, 270 ft. long by 45 ft. wide, descends from Lake Erie to Lake Ontario with a definite, although small, volume of commerce, perhaps showing a maximum of 3 500 000 tons per year; and 2 000-ton vessels passing through the Welland Canal go on down to Montreal through the Laurentian Canals which have drafts and locks much the same as those of the Welland. The New York State Barge Canal leaving the Niagara River at Tonawanda, N. Y., a few miles below Buffalo, is an escape to the Hudson River, and thence to salt water in the Port of New York. The Illinois Waterway at present under construction, will pass through the Drainage Canal at Chicago to the Des Plaines and Illinois Rivers with 9-ft. drafts and thence by the Mississippi River to the Gulf of Mexico. The use of any one of these three canals involves either the utilization of light-draft vessels on the Great Lakes or transshipment from the deep-draft lake carriers. Neither of these alternatives makes for the most economic through transportation.

The Welland Ship Canal

Before discussing the various deep waterways to the sea, proposed a quarter of a century ago, it may be desirable to note the near completion of the new Welland Ship Canal, assume that this is the year 1930, and continue toward Montreal on the 600-ft. freighter down-bound from Duluth.

The Welland Canal entrance is at Port Colborne. It is protected from storms, and mooring space is provided by an extension of breakwaters and piers for a distance of more than 1 mile out into Lake Erie. The entrance to this harbor and the harbor itself are dredged to a depth of 30 ft. below ordinary Lake Erie level. The object of this dredging is to provide for the tilting of Lake Erie in storm-time, so that when the water level drops 5 ft., vessels drawing 25 ft. of water may still enter the harbor. This deep dredging is continued to the Guard Lock, 2 miles from the harbor entrance, where vessels will descend normally about 5 ft. The inner summit canal has a depth of 25 ft., a bottom width of 200 ft., and slopes of various inclinations—the normal water surface width being 305 ft. The canal has a cross-sectional area of 6 000 sq. ft. and is capable of passing, without obstructive currents, about 10 000 cu. ft. per sec. The water-power capacity of this canal will be touched upon later in discussing Niagara River power.

Lift Lock No. 7 is 20 miles from the Erie Harbor entrance. The descent in this lock is, as in the remaining six locks, 46.5 ft.; and the chamber in all the locks is 800 ft. long by 80 ft. wide, with 30 ft. depth capacity. Another ½ mile brings the 600-ft. freighter to tandem Locks Nos. 6, 5, and 4, which are twin locks, as well. The twinning of these locks is necessitated by water supply conditions, all other locks being single-chamber locks. After 5 miles of further travel, including the passing of Locks Nos. 3, 2, and 1, the freighter has descended 326 ft. to Lake Ontario level, which is normally about 246 ft. above mean tide at New York; then 9 600 ft. through a broad canal and an inner harbor—over 1 mile long and 800 ft. wide, with adequate mooring space—to the 400-ft. entrance into Lake Ontario.

The work done on the Welland Canal in its various elements represents the highest engineering achievement. As already stated, it will be completed about 1930 and will cost upward of $100 000 000. The original undertaking was pre-war and the ultimate expenditure of so much money as the final cost was not anticipated. Whether or not the St. Lawrence River itself is canalized for sea-going vessels, this adequate link over the Niagara Escarpment brings Lake Ontario into the deep-water basin of the Great Lakes System leading to Buffalo, Detroit, Chicago, Port Arthur, and Duluth. The estimated time consumed in passing through this 27 miles of waterway, including harbors at each end, is about 12 hours.

Port Weller to St. Lawrence

From Port Weller, the Lake Ontario exit from the Welland Canal, the course is straightaway toward Tibbetts Point at the head of the St. Lawrence River, 156 miles distant. Northerly from Port Weller is the Canadian City of Toronto, 29 miles away; and the City of Hamilton is about the same distance to the westward. Charlotte, the lake port of the City of Rochester, N. Y., is 92 miles to the eastward, while Oswego, N. Y., the Lake Ontario entrance to the New York State Barge Canal, is 141 miles to the eastward of Port Weller. Lake Ontario has depths exceeding 600 ft.

Upper St. Lawrence

The 600-ft. freighter passes the Tibbetts Point Lighthouse and enters the St. Lawrence River, 14 hours after leaving Port Weller—1 157 miles and 115 hours from Duluth. At its head the river is 10 miles across from the New York shore to the Ontario mainland, with the waterway split by islands occupying 6 miles of the width. The formation here is igneous with characteristic pinnacle rocks forming submerged obstructions and creating the Thousand Islands. This condition extends down stream 51 miles to Morristown, N. Y. It should be understood that the description of channels relates to the usual vessel track, crossing back and forth in some places over the International Boundary. In this 51-mile reach natural channel depths range from 30 to 180 ft., and the deep vessel right of way is 1 000 ft. or more in width—except that a 7-mile stretch from Thousand Islands Park to Alexandria Bay and a 3-mile stretch, beginning 4 miles above Brockville, Ont. (which is 1 mile above Morristown), have widths ranging from 300 to 600 ft.—but with very deep water. (See Fig. 6.) Some cleaning up is indicated in this 10 miles of right of way.

Below Morristown, the river flows 50 ft. deep and ¾ mile or more wide for a distance of 11 miles to Prescott, Ont., and Ogdensburg, N. Y.—at the mouth of the Oswegatchie River. These cities are 62 miles down the St. Lawrence—1 219 miles and 120 hours, or 5 days—from Duluth.

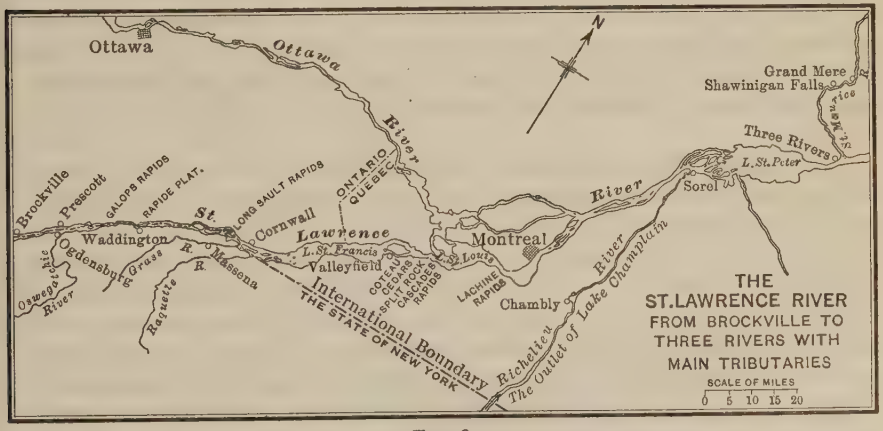

Fig. 6.

The deep wide river extends 3.5 miles down stream from Prescott to the entrance of the Canadian Cut known as the North Channel—with the head of the Galops Rapids 3 miles farther down stream. On the New York side, a deep channel extends 6 miles to the head of the American Galops Rapids. A limestone ledge, overlaid in part with glacial drift, forms the natural weir which creates Lake Ontario. (See Plate V.) The upper 69 miles of the St. Lawrence River is hydraulically an arm of the lake—with an open-season descent of only 1 ft. from lake level to river level at Ogdensburg.

As the St. Lawrence River takes a general northeasterly course, it is well to note the fact that the latitude of Ogdensburg is 44° 42′, and the latitude

of Liverpool is 53° 24′—so that Liverpool is still 600 miles to the north of Ogdensburg; and when an ocean liner finally passes from the Gulf of St. Lawrence into the open Atlantic, it is still 100 miles to the south of Liverpool, and about 200 miles to the north of Havre.

International Rapids Section

The zero point for the Rapids Section of the St. Lawrence Waterway begins about 4 miles below Ogdensburg. It is desirable to note the characteristics of the St. Lawrence River and the flanking canals used by lake-going vessels with a draft of 14 ft. and carrying perhaps 2 000 tons of freight.

Down-bound vessels pass through the North Channel, an artificial rock cut, for a distance of 1½ miles, then another 1½ miles to the entrance of the Galops Canal at the head of the Galops Rapids. Some down-bound vessels chute the rapids following an improved channel through the rock barrier. Up-bound vessels take the Galops Canal. The descent in the Galops Rapids is 8 ft. in a distance of 3 miles. The canal extends for a distance of 7 miles flanking the swift, curving river, descending 14 ft. in the terminal lock.

At the Town of Iroquois, Ont., vessels enter the river again, following the deep channel in a swift current for a distance of 4 miles to the entrance of the Morrisburg Canal at the head of Rapide Plat. This canal has a length of 4 miles, making a descent of 12 ft. in the locks at Morrisburg, Ont. Down-bound freighters sometimes chute these rapids. The visible bottom in the upper portion of these rapids is of red sandstone and it is in this vicinity that the engineers of the International Joint Commission have recommended regulating works, for the maintenance of Upper St. Lawrence River and Lake Ontario levels, the creation of storage, and the manual control of the water supplied to the river.

After passing through 10 miles of swift-flowing river with depths of 20 to 40 ft. or more, the narrow channel and swift current at Croil's Island is reached. Down-bound vessels follow the river through this swift water, descending 3 ft. in less than 1 mile, while up-bound vessels take the flanking Farran's Point Canal. At the head of Croil's Island, the channel splits, leading to the right toward the South Passage of the Long Sault Rapids and the entrance 4 miles down from the splitting point to the Massena Power Canal. Vessels passing out of the Farran's Point Lock take the capacious, deep, north channel for a distance of 4.5 miles to the entrance of the Cornwall Canal and the head of the Long Sault Rapids. Only a few passenger steamers chute these and the other magnificent rapids between this point and Montreal. The Cornwall Canal makes a descent of 50 ft. in 11.5 miles. The Long Sault Rapids make the major descent in a main-channel distance of 3 miles. The descent to Lake St. Francis, with a volume flow of 230 000 cu. ft. per sec., creates the dominant water power of the International Section of the St. Lawrence River.

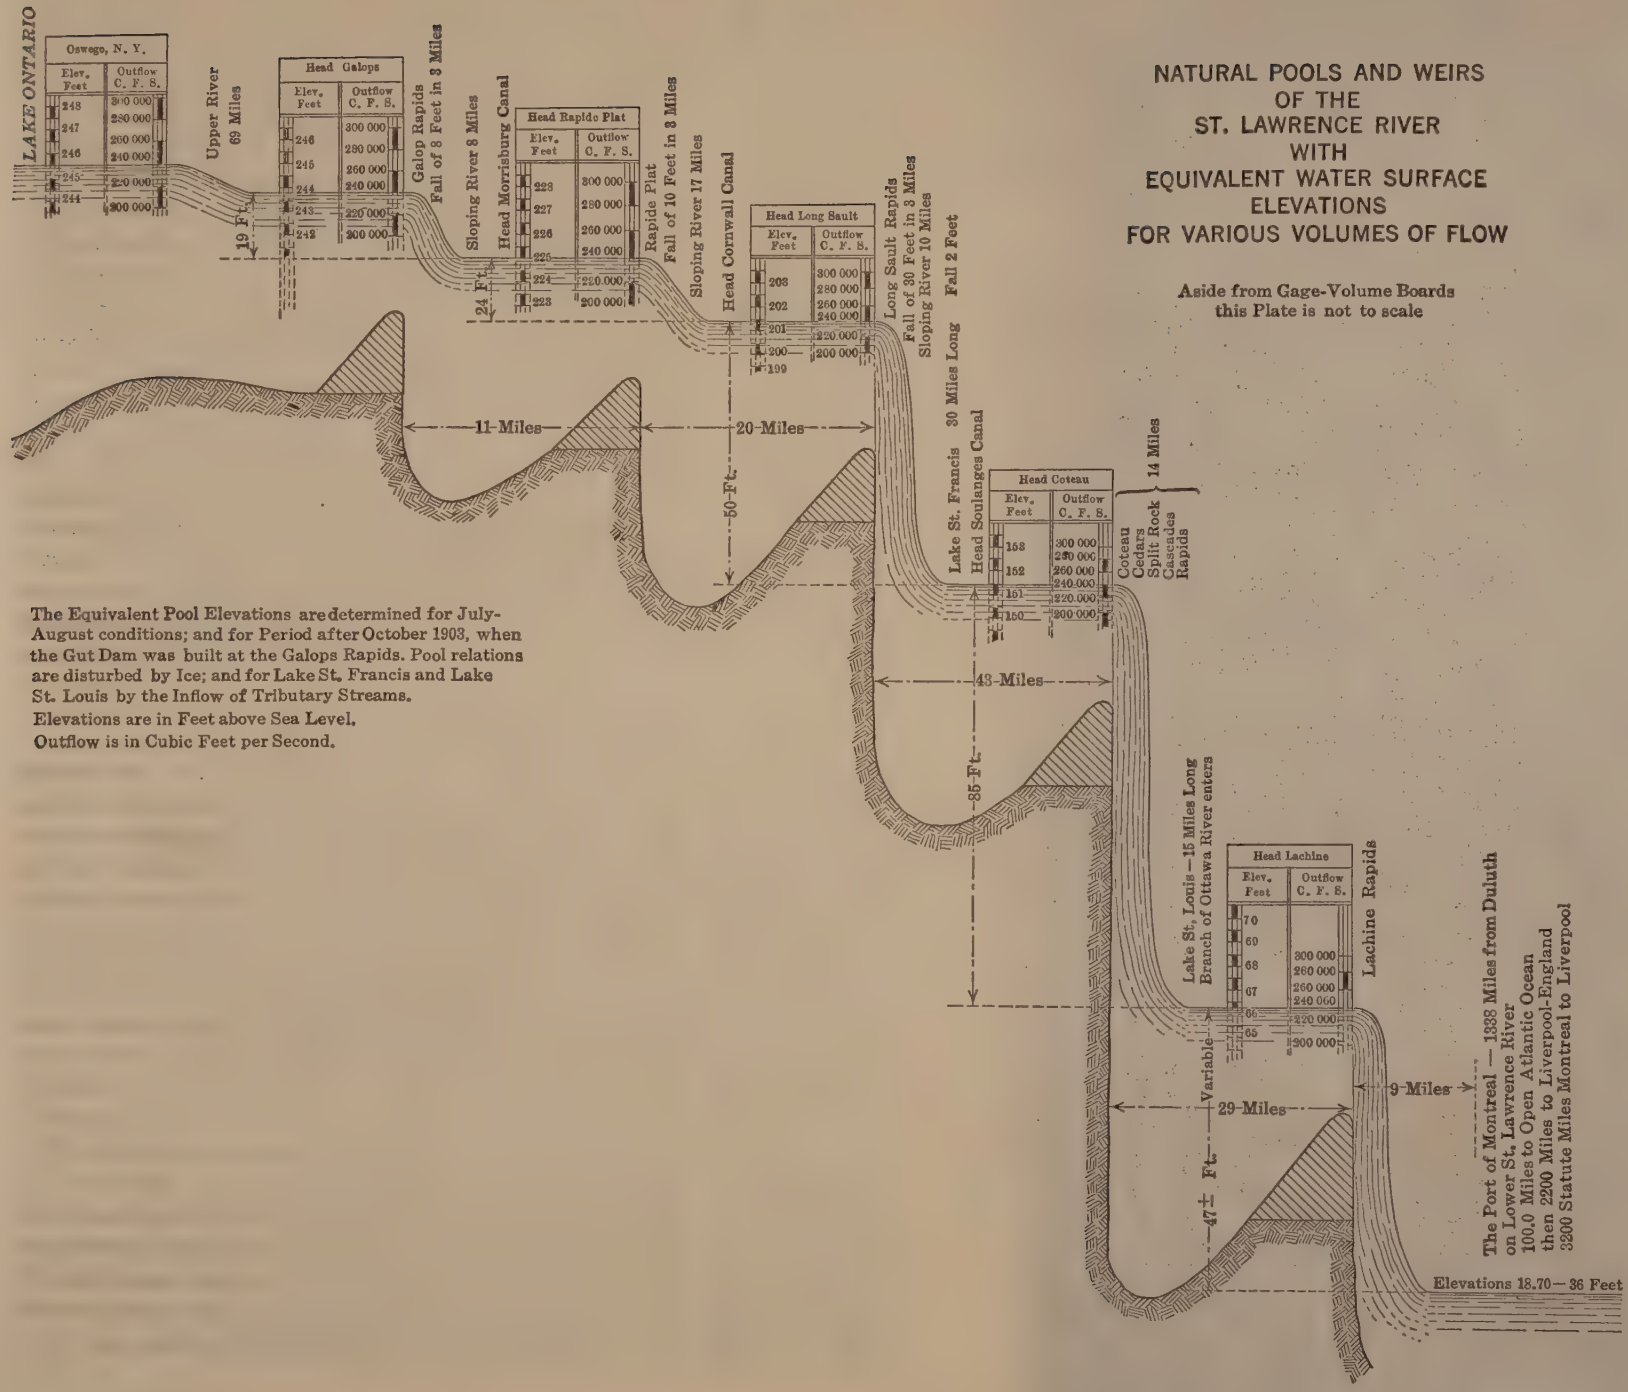
The Canadian Rapids Section

About 1.5 miles below the lowermost lock at Cornwall, Ont., the International Boundary Line leaves the St. Lawrence River and proceeds overland, following eastward on the 45° parallel of latitude.

PLATE V.
TRANS., AM. SOC. CIV. ENGRS.
VOL. 89, PAPER No. 1580.
SHENEHON ON
THE ST. LAWRENCE WATERWAY
TO THE SEA.

NATURAL POOLS AND WEIRS OF THE ST. LAWRENCE RIVER WITH EQUIVALENT WATER SURFACE ELEVATIONS FOR VARIOUS VOLUMES OF FLOW

Aside from Gage-Volume Boards this Plate is not to scale



The Equivalent Pool Elevations are determined for July-August conditions; and for Period after October 1903, when the Gut Dam was built at the Galops Rapids. Pool relations are disturbed by Ice; and for Lake St. Francis and Lake St. Louis by the Inflow of Tributary Streams.
Elevations are in Feet above Sea Level.
Outflow is in Cubic Feet per Second.

From this point, 46.5 miles below the zero point of the International Rapids Section, the Canadian National Section begins. This is at the head of Lake St. Francis and is 50.5 miles down stream from Ogdensburg and Prescott and 1 270 miles from Duluth. From the level of the St. Lawrence River at the head of the Galops Rapids, the descent to the head of Lake St. Francis is 91 ft.; and Lake St. Francis is still 152 ft. above sea level.

The conditions in the Canadian National Section are exceedingly simple: First, Lake St. Francis—30 miles long, with a width of 1 mile to 5 miles, and water abundantly deep for 25-ft. navigation—with the exception of about 3 miles which need dredging or cleaning up. The total area of the lake is about 90 sq. miles which will give excellent forebay capacity for peak-load operation of hydro-electric plants in the tandem rapids at its foot. These outflow rapids in series, beginning at the entrance of the Soulange Canal at Coteau Landing, are the Coteau, the Cedars, the Split-Rock, and the Cascades—the full series making a descent in 14 miles of 84 ft. to Lake St. Louis. Lake St. Louis is another capacious, deep lake, 15 miles long, with widths ranging from 1 mile to 6 miles. It has a forebay value of over 50 sq. miles to stabilize varying volumes of flow in the hydro-electric plants of the future in the outflowing Lachine Rapids. The Lachine Rapids, beginning at the head of the Lachine Canal, make a normal descent of 45 ft. in 9 miles to the Lower St. Lawrence at the ocean port of Montreal—with the Atlantic 1 000 miles away down a magnificent, still-flowing river—with 30-ft. drafts on the trans-Atlantic liners an accomplished fact.

The Port of Montreal

The Port of Montreal has been created by the expenditure of nearly $40 000 000. It has deep-draft berths to accommodate more than 100 large modern ocean steamships simultaneously, with more than 8 miles of wharves and piers capable of docking vessels drawing over 25 ft., and more than 5 miles of these will receive vessels drawing 30 ft. and over; 60 miles of railway tracks to serve these wharves; 35 of these steamship berths are modern concrete wharves built in the past few years; 4 large modern fire-proof elevators with a capacity of 12 000 000 bushels, having conveyor systems to 26 steamship berths at which 19 vessels can be loaded with grain at one time; 24 permanent fire-proof transit sheds; modern cold storage warehouse; complete and valuable construction and repair plants; and near-by shipbuilding plants, including a dry dock. These facts are taken from the 1923 report of the Montreal Harbor Commission.

Having in mind the large financial investment in creating the modern facilities of a great terminal port, where vessels discharge their import cargoes for transshipment to smaller lake vessels or to rail carriers, and where large quantities of freight for export are received from the Great Lakes either by the small canal type of vessel or by rail, it may be readily appreciated why Montreal may view apprehensively the creation of a deep-draft waterway interfering with this great and profitable business of transshipment. The

situation here is somewhat the same as the situation in Buffalo, the present down-bound Lake Erie terminal of the Great Lakes, where cargoes are transshipped to barges of the New York State Canal or to railway carriers.

Since the waterway to the sea between Duluth and Montreal contemplates through shipment without stopping at Montreal for other than supplies, no further detailed statement of the harbor at Montreal is desirable in this paper.

However, as Montreal is the eastern limit of the contemplated improvement, the conditions of navigation and its strategic position with respect to the seaports of the world will be reviewed, before touching on other avenues to the sea, and before discussing the proposed constructions for navigation and water power in the Rapids Sections of the St. Lawrence River for a distance of 115 miles up stream from this port.

St. Lawrence Ship Channel

Below Montreal, dredged channels, 450 ft. wide, with greater widths on curves, and with depths ranging from 30 to 35 ft., are encountered for a distance of 150 miles to Quebec and for a further distance of 175 miles to Father Point, Que. Below this are few dredged areas. At Three Rivers, Que., 80 miles below Montreal, tidal movements are discernible. To April, 1921, the Dominion Government had expended about $24 000 000 on the St. Lawrence Ship Channel below Montreal. The season of navigation begins in late April and ends in early December, having a normal length of 224 days, or 61% of the year. The hazards of navigation are not large and insurance rates will not be prohibitive.

Montreal's Strategic Position

The Port of Montreal is 370 miles nearer Liverpool than the Port of New York. The distance to Gibraltar, the gateway to Mediterranean ports and to the Suez Canal, is approximately the same for the two ports. From the foot of Lake Erie to Liverpool by way of New York is 443 miles by rail and 3 576 miles by sea, a total of 4 019 miles; while the all-water route through the St. Lawrence is 350 miles shorter. The loss of time in passing through the Welland Canal—about 9 hours more than in open channel running—and the loss of time in the St. Lawrence River Section—perhaps 9 hours more—are probably less than the time lost in transshipping cargoes. The handicap of any water route in northern latitudes is the embargo of the ice season of 140 days.

Montreal Commerce

The 1923 commerce of the Port of Montreal amounted to 6 372 400 tons, the exports being a little less than twice the imports. The imports, however, were mostly from the United States and consisted largely of coal and petroleum. The dominant export cargo is wheat and other grains, showing a total volume of 3 278 100 tons out of the total export volume of 4 152 900 tons. Other large exports are automobiles and parts, dairy products, flour—346 100 tons—fruit, and meats. Of the exports of wheat and other grains amounting to 120 108 000

bushels in 1923, nearly 75 000 000 bushels reached Montreal by boat. During the same year, the Port of Buffalo received by lake 182 000 000 bushels, of which 114 000 000 bushels were Canadian grain. It is interesting to note the fact that 294 000 000 bushels of grain were shipped from the Canadian Lake Superior Ports of Fort William and Port Arthur between September 1, 1922, and September 1, 1923. A part of this grain was moved by rail. It is also interesting to note that the Duluth-Superior Port shipped in 1923 about 70 000 000 bushels of grain and that the volume of grain passing through the locks at Sault Ste. Marie in 1923 was about 370 000 000. During 1923 Buffalo shipped by the Erie Canal about 20 000 000 bushels of wheat. The total commerce through the Erie Canal was 1 626 100 tons in 1923.

If the value of exports in the Port of Montreal is taken as $50 per ton, the total valuation appears to be $200 000 000.

Lake-and-Ocean Vessels

It will be assumed that engineers will solve the problem of composite vessels to traverse the fresh-water seas and the salt seas; that the evolution of this vessel will come in the ten years between the definite decision to construct the waterway and its completion; and if not in this decade then in some of the early decades of the century. Such a vessel was designed nearly a quarter of a century ago by an eminent naval architect and shipbuilder of Detroit, Frank E. Kirby, and his conclusions—published in 1900 in the report of the Board of Engineers on Deep Waterways—indicated the cost to be practically 10% more than the cost of a vessel built for exclusively Great Lakes navigation. Any economies in transportation by the opening of this waterway might be cancelled by the time losses, by the cargo damage and losses, and by the labor and overhead costs of transshipment. The scheme of water transportation connecting Liverpool, Continental Atlantic, and Mediterranean ports, must contemplate fundamentally the continuous movement of an unbroken cargo. It should be understood that special types of boats will continue in special service, such as ore and coal-carrying, between Lake Superior and Lake Erie ports. It is of little concern whether the Rapids Section of the St. Lawrence Waterway to the Sea has, in its first decade, a commerce of 5 000 000 tons or 20 000 000 tons. The analysis of possible traffic and the savings to be made by a through route from Duluth or Chicago to Montreal and overseas is interminable and speculative. It will appear that the construction of this waterway is inevitable, that the cost will be largely carried by the co-ordinately developed water power, and that a demonstration of its commercial feasibility is unnecessary.

Other Waterways to the Sea

Turning briefly to deep waterways other than through Montreal to pass from the Great Lakes to the Atlantic, it should be recalled that under an Act of Congress of February, 1895, a Deep Waterways Commission was appointed to make a preliminary inquiry concerning waterways between the ocean and the Great Lakes. It was provided that the commissioners appointed under this

Act should serve without compensation. The Commission appointed by the President of the United States consisted of James B. Angell, then President of the University of Michigan, John E. Russell, and Lyman E. Cooley. This Commission made an investigation from existing sources of information and reported voluminously in 1897.*

This Commission recommended the appointment of a Board of Engineers on Deep Waterways. Congress acted on this recommendation and made appropriations ultimately aggregating nearly $500 000. The Board of Engineers appointed consisted of the late Charles W. Raymond, Major, Corps of Engineers, U. S. Army, M. Am. Soc. C. E., Alfred Noble, Past-President, Am. Soc. C. E., and George Y. Wisner, M. Am. Soc. C. E. This Board, after two years of surveys, examinations, investigations, and studies, reported in June, 1900.† The report is probably the most elaborate existing discussion of the elements entering into deep waterways.

Routes

The routes contemplated by the Board of Engineers take into consideration the Great Lakes System from Duluth and Chicago to the foot of Lake Erie, with Lake Erie regulated. The descent over the Niagara Escarpment followed the Niagara River to Lasalle, N. Y., for a distance of 16 miles below Buffalo and re-entered the Lower Niagara River at Lewiston, N. Y., substantially at Lake Ontario level, 25 miles from the regulating works at Buffalo; then proceeded through the deep, spacious Lower Niagara River and Lake Ontario to Oswego 139 miles away. Here the canalization climbed up 133 ft. by lockages to the level of Oneida Lake and followed the Mohawk Valley descending to the Hudson at Troy, N. Y. From Troy to the Battery in New York it follows the established tidal Hudson River route for a distance of 140 miles. This route beginning at Oswego and ending in the Port of New York will be referred to as the Oswego-Mohawk Route.

Another route followed Lake Ontario past Oswego, entered the St. Lawrence River at Tibbetts Point, and proceeded to the Galops Rapids. Here, the route followed through a series of river channels and canals, including four ship locks, to Lake St. Francis at the International Boundary. The route then crossed the Boundary Line and followed for a distance of nearly 30 miles down Lake St. Francis to a point on the south bank of the lake opposite Coteau Landing and near the head of the Coteau Rapids. The route then proceeded through the divide for a distance of 40 miles in Canadian territory and for a further distance of 8 miles in American territory to Kings Bay, Lake Champlain—15 miles north of Plattsburg, N. Y. Lake Champlain is about 50 ft. lower in elevation than Lake St. Francis and the descent is made in five ship locks. The route then proceeded 124 miles through deep water in Lake Champlain and through canalized waterways and entered the upper courses of the Hudson River below Fort Edward, N. Y. It met the Oswego-Mohawk route at Troy and proceeded to New York through the tidal Hudson.

* H. R. Doc. No. 192, 54th Cong., 2d Session.
† H. R. Doc. No. 149, 56th Cong., 2d Session.

Preferred Routes

The Board of Engineers on Deep Waterways recommended the route by the way of Oswego; but since that time the Dominion Government has undertaken and is completing the construction of the new Welland Ship Canal over the Niagara Escarpment, and the development of the St. Lawrence itself to the foot of Lake St. Francis and beyond to Montreal is recommended. The International Section of the St. Lawrence Waterway to the Sea will be subsidized by water power, and may be eliminated in any estimate of cost chargeable to navigation.

Duluth, Chicago, Montreal, and New York

The preferred route from the Great Lake System to the Port of New York for deep-draft ocean-going vessels now appears to be the St. Lawrence-Champlain Route; and the aspirations of the citizens of New York for a deep waterway, entering salt water through the Hudson River portal, appears to be in parallel with the aspirations of those seeking a deep waterway following the St. Lawrence River to the Atlantic. The trunk line is the same for both routes from Duluth for a distance of nearly 1 300 miles, the dividing point being 40 miles above Montreal.

Comparison of Routes

Having in mind this most remarkable community of interest between the State of New York and other States tributary to the Great Lakes, it is well to compare the Oswego-Mohawk and the St. Lawrence-Champlain routes to the sea. From Oswego to the Battery in New York through Oneida Lake and the Mohawk Valley is 313 miles, involving the passage of 31 ship locks, and requires about 46 hours. Reduced roughly to 1924 prices—assumed to be about 50% more than those of 1900—a waterway with 25-ft. depths in canals, canalized rivers, and lakes, and with ship locks, 740 ft. long, 80 ft. wide, and 30 ft. deep, would cost approximately $287 000 000.

By the St. Lawrence-Champlain Route, from the division point at the foot of Lake St. Francis, the distance to New York is 363 miles, involving a descent through 12 ship locks, and requires 42 hours. The cost, reduced to 1924 prices, would be about $221 000 000.

From Buffalo, the distance to New York by the Oswego-Mohawk route is 477 miles, requiring 64 hours' travel. From Buffalo by the St. Lawrence-Champlain route to New York is 685 miles, requiring 76 hours of travel. The St. Lawrence-Champlain route from Buffalo to New York is 208 miles longer than by the way of the Oswego-Mohawk route; and it takes 12 hours longer to traverse it. On the other hand, it costs $66 000 000 less than the shorter route. It would have the advantage of traversing and serving additional territory in New York and New England; and it would not conflict physically with the permanent use of the Barge Canal. If 1924 prices are taken as 75% more than those of 1900, the Oswego-Mohawk route would now cost $335 000 000 and the St. Lawrence-Champlain route $77 000 000 less.

Other Proposed Routes

No other outlet proposed for deep-draft navigation to the sea needs more than casual mention. The Georgian Bay Canal, planned to depart from Lake Huron through the French River, and to pass over the divide to the Ottawa River and thence to Montreal, appears to be disadvantageous in cost, short season of navigation, and in the fact that it would short-circuit the important traffic cities of the Detroit River, Lake Erie, and Lake Ontario. A railway to Hudson Bay has long been advocated and considerable money spent in surveys and investigations. The short season of navigation—about 150 days—and the transshipping elements, are probably fatal to this route in competition with all-water routes.

The St. Lawrence-Montreal Project

The project contemplated in the report of the International Commission* will be lightly touched upon. The investigations of the engineers were limited to a single year, a period much too short to reach other than tentative conclusions.† A new International Board of Engineers has been appointed to review the project, to report in October, 1925. The personnel of the United States and Canadian Government Engineers reporting to the International Joint Commission in June, 1921, was, as follows: For the United States: W. P. Wooten, Colonel, Corps of Engineers, U. S. Army, M. Am. Soc. C. E., H. G. Roby, M. Am. Soc. C. E., Assistant; for Canada: The late W. A. Bowden, M. C. I. E., D. W. McLachlan, Assoc. M. Am. Soc. C. E., Assistant.

Canadian Section

It appears to the writer that the treatment of the St. Lawrence River for navigation and water power from the foot of Lake St. Francis, with a descent of 83 ft. to Lake St. Louis and from Lake St. Louis with a descent of 45 ft. or more to the river at Montreal, is a matter for the Dominion Government to decide. The recommended project contemplates by-passing in lateral canals the rapids from Lake St. Francis to Lake St. Louis and from Lake St. Louis to the lower river. The two proposed 25-ft. depth canals have lengths of 26½ miles and require three lift locks and two guard locks. These locks would have a usable length of 800 ft., be 80 ft. wide, and 30 ft. deep over the breast-walls. The total estimated cost for these two portions of the Canadian National Section is $92 373 000.

The proposed project contributes nothing toward the ultimate water-power development—stated to be 2 420 000 e. h. p.—in these two great descents. The solution of the problem has been based on the absence of a market capable of absorbing the great volume of visible water power in the St. Lawrence River. An alternate navigation route shown in the plans, follows the river channels through the rapids. This would involve the construction of at least three dams, each 40 ft. or more in height, creating deep slack-water pools, with ship locks passing through each dam to the pool below. From the point of view of navigation this appears sounder than the use of lateral canals, but the build-

* Senate Doc. No. 114, 67th Cong., 2d Session.

† The report of the engineers is printed in Senate Doc. No. 179, 67th Cong., 2d Session.

ing of these dams, in the view of the engineers, should await a receptive market for the electric current produced.

It is the writer's conviction that water power should subsidize navigation. The undertaking is, therefore, a commercial project and the United States does not need to contribute toward the cost. The water power belongs to Canada and ultimately should do its share toward financing the necessary ship locks. The solution of the ice problem of the St. Lawrence River probably means the eventual elimination of all rapids.

It appears from the report of the engineers of the Joint Board, that the alternate navigation route following the river channel, with one or two dams in the Lachine Rapids, would cost $7 000 000 more than the navigation route by 13 miles of lateral canals; and the alternate navigation route through the rapids from Lake St. Louis to Lake St. Francis, with two dams in the rapids, would cost $13 119 000 more than through 13½ miles of lateral canals. The addition of $20 119 000 to a navigation project estimated to cost $92 400 000 should be given careful consideration, provided the slack-water pools created give ampler and faster navigable ways, and provided the total cost of the improvement and its maintenance may be paid eventually by water-power rentals. It is difficult to understand how a project of lateral canals, in no wise aiding water-power development, is logically chargeable to anything else than transportation. If, on the other hand, the best and largest water-power development incidentally creates navigable ways—only the operation and maintenance expenditures and interest on the cost of four ship locks—perhaps $20 000 000—are chargeable to navigation. The operation, maintenance, and depreciation estimated by the Commission for 26½ miles of 25-ft. lateral canals—with all permanent structures built for ultimate 30-ft. drafts—is $750 000 per year. This is 0.8% of the capital cost. For the alternate project of river channel slack-water pools this sum should be less. These comments are based on the proposition that all constructions for the navigable waterway should be steps toward and be chargeable to water-power development. The expenditure of $1 158 000 on dredging in the Canadian National Section of Lake St. Francis needs mention only.

International Section

Division No. 4 of the Commission report embraces the International Rapids Section, from the boundary line at the head of Lake St. Francis to the deep river about 5 miles up stream from the Galops Rapids, covering a distance of 48 miles with a difference of 91 ft. in elevation. Beginning at the head of the Galops Rapids the descent to the head of Rapide Plat—11 miles down stream—is 19 ft.; from this point to the head of the Long Sault Rapids the descent—in 20 miles—is 24 ft.; and from the head of the Long Sault to the boundary in Lake St. Francis, the descent is 48 ft. in 13 miles. (See Plate V.) The International Joint Commission project for navigation provides a lateral canal, 6 miles long, with two locks, on the Canadian side of the river, following in part the present alignment of the Cornwall Canal around the

Long Sault Rapids. A dam at the head of Barnhart Island, raises by 30 ft. the present level of the pool at the head of the Long Sault Rapids to Elevation 231. This gives a total lift from the head of Lake St. Francis of 78 ft. at normal flow stage; and a total power fall of 76 ft. This slack-waters the river for a distance of 17 miles to the foot of a regulating dam in Rapide Plat. The summer slope in the river in this 17 miles would be about 1 ft. Here, vessels pass through a ship lock, with a lift of 15 ft. to Elevation 247, which is within 1 ft. of the regulated level of Lake Ontario. The regulating dam slack-waters the river to the zero point at the entrance to the North Channel—drowning out the Galops Rapids. The reformed International Section then consists of 41 miles of open-river running, 7 miles of canals, and 3 ship locks.

Duluth to Liverpool

For the whole Rapids Section from the zero point at the North Channel, 3 miles above the Galops Rapids, to Montreal—a distance of 115 miles—the reformed waterway shows 81 miles of open river running, 33 miles of canals, 7 lift locks, and 2 guard locks. An ocean-going vessel with a normal speed of 11 miles per hour will require 20 hours to traverse the Rapids Section to Montreal. This then shows from Duluth to Montreal, 1 338 miles and 140 hours, or 5 days and 20 hours, in transit. The average speed is about 9½ miles per hour. The Board of Engineers on Deep Waterways in discussing the various waterways to the sea based the time on a vessel traveling in open running 12½ miles per hour—and the Board used a quicker locking schedule than the writer. Using the Board's values the time from Duluth to Montreal would be 124 hours, or 5 days and 4 hours. Adding for Montreal to Liverpool 10 days and 20 hours, shows 16 days in transit; and with a day at each end for lay-over—loading at Duluth and unloading at Liverpool—shows a total time of 18 days. With a cargo of 10 000 tons, the work done is 45 400 000 ton-miles. It is probable that bulk freight may be carried between Duluth and Liverpool at a rate not exceeding 0.7 mills per ton-mile, or $3.18 per ton. This means for wheat a rate of about 10 cents per bushel. The rate in 1923 through St. Marys Falls Canal was 3.8 cents per bushel from Superior to Erie ports, including loading and unloading.

Exporting Raw Materials

An economic principle enters in considering a project which facilitates the export of raw materials. This principle was enunciated by the millers of both the United States and Canada at the time of the hearings before the International Joint Commission: A country's prosperity lies in converting, in its own domain, raw materials into finished products. Wheat should not be exported until it has been converted into flour. The flour mill employs labor, it employs the makers of machinery, sacks, and barrels. It sends the feed-stuffs to the farm for poultry and cattle. Export flour, dairy products, poultry, beef—not wheat; export—not ore—but steel!

It is not improbable that on the completion of a waterway to the sea a special type of vessel will carry flour direct from the Great Lakes ports to overseas ports. The present discrimination of rates on flour, as compared with wheat, seriously handicaps export flour trade. In 1923 the total exports of wheat flour from the United States as reported by the Department of Commerce, amounted to 16 310 000 bbl. Of this, 5 218 000 bbl. passed through the Port of New York. During the same year the export of wheat amounted to 98 523 000 bushels. In 1921 the export of wheat was 280 058 000 and, in 1922, 164 692 000 bushels. The largest portions of the 1921 exportation went to Belgium, France, Germany, Italy, The Netherlands, and England, a considerable portion going to Canada, doubtless for export through the Port of Montreal. The largest portion of flour exports goes to the same countries, with additional exports to China and Japan.

Waterway Desirable

The immediate construction of the final link of the navigable waterway from the foot of Lake St. Francis to Montreal at a cost of about $100 000 000, the United States sharing in this expenditure, will probably be in the interest of economic transportation for overseas trade. The most careful investigation, however, should be made, weighing the desirability of spending all the money in a way helpful to ultimate water power. If a somewhat larger expenditure will count toward the water-power development of a decade later, it may be advisable to make this larger expenditure now. The part of the United States would then be to pay the interest on a portion of the bonds until water-power rentals do so.

Water Power and Navigation

Water-power projects are sometimes suspected of wearing the guise of navigation projects. A navigation project appeals more strongly to the minds of the people in the trade districts tributary to the Great Lakes far from the water power. The radius of economic benefits from water power may be limited to 200 miles, while the economic benefits of navigation, reaching the west through Chicago, Duluth, and Port Arthur, may have a radius of 2 000 miles. Many of the people looking for benefits in transportation find it difficult to understand that a project may be dual—that the development of the navigable waterway and the development of the water power go hand in hand, each assisting the other. If the water-power element of the St. Lawrence Waterway to the Sea is too greatly accentuated, it arouses suspicion in the minds of the people of the agricultural regions of the Middle West. It is best, however, to state the case as it exists.

Water Power

The Government engineers find the total potential energy available in the Rapids Section of the St. Lawrence River to be 4 064 000 e. h. p. This is as follows:

Canadian:	Lachine Rapids	860 000 e. h. p.
	Coteau, Cedars, Split-Rock, Cascades	1 560 000 " " "
	Total	2 420 000 e. h. p.
International:	Long Sault Rapids, initial	1 464 000 e. h. p.
	" " " , later	180 000 " " "
	Total	1 644 000 e. h. p.
	Rapids Section, Grand total	4 064 000 e. h. p.

These estimates of potential power are based on a volume of continuous flow of 210 000 sec-ft.; and the use of an over-all efficiency of 88%, with the performance of new units at Niagara Falls as a precedent for this high efficiency. Only the development of 1 464 000 e. h. p. in the Long Sault Rapids, amounting to 36% of the whole, is contemplated in the initial project. Of this amount, 58 000 e. h. p. is to care for existing needs of the Massena Plant of the Aluminum Company of America.

The volume of continuous or prime flow, taken as 210 000 sec-ft., assumes the diversion in the Drainage Canal at Chicago as discontinued. The writer believes it is safer to assume that the diversion of 10 000 sec-ft. will continue at Chicago for a number of years. The available continuous or low-water flow, as determined by the Government engineers, may be taken as 200 000 cu. ft. per sec. Perhaps the over-all efficiency of 88% is somewhat optimistic. The writer prefers 84 per cent. With these values the available prime power in the St. Lawrence River becomes 2 190 000 e. h. p. in the Canadian Section and 1 410 000 e. h. p. in the International Section. This latter value assumes a head of 74 ft. for all water used at the Long Sault Rapids.

Heads

The heads estimated by the Government engineers in deriving the values first stated are for the Lachine Rapids, 41 ft.; for the Coteau, Cedars, Split-Rock, and Cascade Rapids, 74 ft.; and, initially, for the Long Sault Rapids, 74 ft. The development at the Long Sault Rapids contemplates the ultimate raising of the head about 8 ft. The limitation on available head comes with the increased slope due to greater frictional resistance of the river running under an ice cover. The following may be regarded as reasonably conservative values for the ultimate winter head:

Canadian:	Lachine Rapids	30 ft.
	Coteau, Cedars, Split-Rock and Cascade Rapids	82 "
	Total	112 ft.
International		88 "
	Total	200 ft.

The reduced slope giving the highest usable head means slower current and less ice trouble during the season of zero weather. The reduction of slopes

with deeper channels and slower velocities is also desirable from the point of view of navigation.

Prime Water

The dependable volume of river flow is a most important element in the determination of the power content of the St. Lawrence River. In a state of Nature, monthly mean volumes range from as low as 190 000 sec-ft. to 320 000 sec-ft. The outflow follows the caprice of natural automatic control of the waters of the Great Lakes. Colonel Wooten found, by a careful investigation, that the use of regulating works on rock foundations at Rapide Plat, would increase the dependable flow to 210 000 sec-ft. In a report on the regulation of the St. Lawrence River, in 1919, the writer reached conclusions which do not differ greatly from those of Colonel Wooten, although his analysis had in mind navigation as prior to water power in benefits.

These studies of the possibilities of making uniform and dependable the flow of the St. Lawrence River are illuminating as pointing out the possibilities of converting secondary power into primary power by conserving the water and stabilizing the flow. It appears that the regulation of Lake Ontario, with a pull-down of 3 ft., adds 20 000 cu. ft. per sec. to the prime outflow of the St. Lawrence River. It is obvious that the full utilization of all the great natural reservoirs of Lakes Superior, Michigan-Huron, and Erie, added to the Lake Ontario reservoir, will yield the largest volume of prime flow. Although Lake Ontario is a considerable reservoir in itself, with an area of 7 240 sq. miles, the combined area of the three other great reservoirs mentioned is more than twelve times as large. The storage reservoirs and forebays of the Great Lakes will be discussed later in some considerable detail. The available dependable prime flow of the St. Lawrence River with full Great Lakes regulation is given in Table 2.

The years included in this hydrological analysis (Table 2) are more precise than earlier years, in the necessary lake elevations. The first year is 1891 and the last, 1924—34 years in all. The gauge readings shown in Column (2) of Table 2 are of January 1 of the year concerned, determined by taking a mean of the mean for the month of December of the year before and of January of the year concerned. They mark the fluctuations of the lakes from the first day of each year to the first day of the following year. They may be regarded as readings on gauges having the following zeros for the several lakes: Lake Superior, 600.5; Lakes Michigan-Huron, 580.0; Lake Erie, 571.0; and Lake Ontario, 245.0. These may not represent the best final values for these gauge zeros, as subsequent analyses made more in detail may indicate slight changes. The values used will give an additional depth of approximately 2 ft. over the improvement planes for navigation in the lakes, except for Superior, where the benefit may be little over 1 ft.

The approximate mean elevations of the various lakes during the important months of navigation, May to November, inclusive, may be 0.7 ft., the cresting elevation, 1 ft., and the annual mean, 0.5 ft., above the mean elevation for January 1 of each year as shown in Column (2) of Table 2.

TABLE 2.—St. Lawrence River Outflow with Great Lakes Regulation.

Year.	Lake surface, gauge readings, in feet.	Water supply, in second-feet.	Outflow, in second-feet.		Storage changes, in second-feet.

The water supply shown in Column (3) of Table 2 is the yield or outflow in the St. Lawrence River after converting the storage changes in the Great Lakes System into second-feet. It is the yield which would have occurred in the absence of any rise or fall in the lake surfaces. It should be understood

in interpreting the water supply that the volume of diversion at Chicago, since the opening of the Drainage Canal in January, 1900, has been credited as outflowing in the St. Lawrence River instead of at Chicago. Account was taken of the lessened outflow of the St. Lawrence River due to natural ice conditions.

The dependable flow with limited rise and fall in the various lakes is 230 000 cu. ft. per sec. It was found that the excess flow, with a mean value of 7 100 sec-ft., is undependable. For periods of from 1 to 9 years no excess water may be available. Storage changes are shown in Columns (6) and (7) of Table 2.

From the volume of prime flow should be deducted 10 000 cu. ft. for Chicago. This leaves 220 000 sec-ft. for continuous water-power uses in the St. Lawrence River. This volume will be available every day of every year and in every desirable hour of every day. The Reservoir System of the Great Lakes will guarantee the mass volume, and the forebay of Lake Ontario will absorb the minor irregularities of this water. The regulation of all the Great Lakes contributes 20 000 cu. ft. per sec. more of prime water than was determined by the Government engineers from the regulation of Lake Ontario alone.

The mean volume of water supply is precise to 2 per cent. It is an even chance whether it is 2% larger or 2% smaller. The mean value of the water supply for each 5-year period has a precision a little less than the mean flow of 34 years. For a single year, the possible error may be as much as 5%, sometimes too large, sometimes too small. The effect of these possible divergences is not cumulative.

The computations of level changes in the various reservoirs and forebays, as shown in Column (2), Table 2, have assumed in all the same depth of storage saving or loss. In practice, the storage in Lakes Erie and Ontario will be used only in low-supply years such as 1891, 1895, 1901, 1910, 1914, 1919, and 1924. In four years out of five, Lakes Erie and Ontario will be maintained at a high level with little surface variation. This will mean a gain of perhaps 1 ft. in head for water-power uses and increased depths in the upper river channels, with beneficial effect on velocities and ice formation.

The mean regulated outflow values of the water supply of the Great Lakes and the yield, in cubic feet per second, for each square mile of tributary drainage basin are given in Table 3.

The supply diverted at Chicago after 1900 is counted as present in Table 3.

Gain by Regulation

It should be accentuated that the gain in electric energy from the increased outflow of 20 000 cu. ft. per sec. is prime power. The installation already estimated by the Government engineers is sufficient to use all the prime water all the time, with some margin for excess water and peak-load use. The increments of power from increased flow, using the same heads as the Govern-

ment engineers, but using the coefficient 84% for over-all efficiency, are as follows:

Canadian: Lachine Rapids	78 000 e. h. p.
Coteau, Cedars, Split-Rock, Cascade Rapids	141 000 " " "
Total, Canadian	219 000 e. h. p.
International Section: Long Sault Rapids	141 000 " " "
Total, St. Lawrence River	360 000 e. h. p.

The installation at the Long Sault contemplates 52 units, each rated at 32 250 e. h. p. on the station busses. At full gate, the turbines are estimated to use 4 580 sec-ft. The total output may be 1 680 000 e. h. p., and the maximum water use is 233 000 sec-ft.

TABLE 3.—St. Lawrence Water Supply and Yield of Great Lakes.

Periods.	Total supply, in second-feet.	Yield per square mile of drainage basin, in second-feet.
1860–1864	241 000	0.838
1865–1869	252 000	0.876
1870–1874	232 000	0.807
1875–1879	249 000	0.866
1880–1884	260 000	0.904
1885–1889	235 000	0.817
Mean of 30 years	245 000	0.852
1891–1895	220 000	0.765
1896–1900	239 800	0.833
1901–1905	244 400	0.850
1906–1910	225 400	0.784
1911–1915	244 800	0.851
1916–1920	251 200	0.871
1921–1924	208 500	0.708
Mean of 34 years	233 700	0.813
Mean of 64 years	239 000	0.831

It will be observed that the installation contemplated is sufficient for the continuous flow of 220 000 cu. ft. per sec., all used in the main power house at the Long Sault Rapids, without any diversion going to Massena. Under this assumption, the prime power to be developed in the Long Sault Rapids under a head of 74 ft. is 1 550 000 e. h. p.

The ultimate capitalized value of the additional 360 000 e. h. p., without additional installation, will not be less than $50 000 000.

Cost of Energy

The estimated cost of the initial power development, including all structures, canals, ship locks, regulating works at Rapide Plat, and channel dredging,

is $159 197 200. The estimated operation and maintenance cost, including depreciation, is $1 782 000 per year. The unit cost is $103 per e. h. p., based on the prime volume of river flow. Let it be assumed that the cost may be $17 per e. h. p. more than estimated. This will care for some over-run, adjust matters with Massena, and take care of additional overheads.

With money at 5% and all other annual expenditures 3%, the possible rental price for the sale of electric power available every year for 365 days and every hour of every day is $9.60 per e. h. p.-year. In case the costs should prove to be $150 per prime e. h. p., the rental price would be $12 per e. h. p.-year. For the lesser cost, the sale price per kilowatt-hour, with 90% utilization, will be 1.63 mills and with 50% utilization, 2.94 mills. For the larger cost, the price per kilowatt-hour, with 90% utilization, is 2.04 mills; and with 50% utilization, 3.67 mills. These rentals will be competitive with those for Niagara Falls power, which the writer is informed, average about $15 per e. h. p.-year, and for new contracts about $20 per e. h. p.-year, on the United States side.

With energy per electric horse power-year selling for $12, it is well to note the value of 1 ft. of additional head. It means 21 000 e. h. p. greater output for installations already paid for. This means not less than $200 000 per year added income, which, capitalized at 5%, shows a value of $4 000 000 per ft. of added head. Where additional head may be had for the expenditure of a less sum than this, it should be secured.

St. Lawrence Ice

The St. Lawrence has a bad name as a stream with ice complications. Frazil accumulates and drowns out lesser and sometimes major rapids. The back-water rise at the foot of the Long Sault Rapids is at times 15 ft. or more. It is believed this frazil formation is due to exposure in the rapids and in the shallow swift river and will terminate with the conversion of the river into a series of deep, still, slack-water pools. The writer has observed the vanishing of the ice in the deep, still St. Lawrence River above Ogdensburg, and in the deep, still St. Marys River above Sault Ste. Marie, Mich. The brilliant sunshine characteristic of late March and early April in these regions, and the temperature of the water mass itself, tend to honeycomb the ice. It breaks into needles and melts. It is spoken of colloquially as "rotting." The unreformed Niagara River is a more serious ice stream than the reformed St. Lawrence. In the Niagara many millions of dollars have been spent in hydro-electric construction, but up to the present time nothing has been done toward fundamental ice protection at Buffalo. Ice engineering is a phase of practice which will have to be given more attention in the future than in the past.

Market for Power

In order to visualize the meaning of the 1 550 000 e. h. p. to be initially developed in the International Section, it is well to compare other installations and other outputs. The allotment of each country will be about 880 000 e. h. p. It is stated* by F. A. Gaby, M. Am. Soc. C. E., Chief Engineer of the Ontario

* *Journal*, Eng. Inst. of Canada, March, 1924, p. 14.

Hydro-Electric Power Commission, that, in 1924, the market for electric current in Ontario is 720 000 e. h. p.; that in 1926 there will be a market for 1 250 000 e. h. p., with a visible shortage of 150 000 e. h. p. in hydro-electric installation; and that the 1934 market will be about 2 650 000 e. h. p. This indicates a forecast of growth of 1 500 000 e. h. p. in 8 years, which is more than doubling the electric current consumed in this period. The market is tributary to both Niagara and St. Lawrence power. The 1924 Year Book of the Commonwealth Edison Company serving the Greater Chicago District shows 1 224 000 e. h. p. operating under a load factor of about 50% to be installed by 1925. The Year Book also shows that the Greater New York District had a maximum load in 1922 of about 1 418 000 e. h. p. The Niagara Falls Power Company of New York has a total installed capacity of 698 400 e. h. p., which is used mostly for electro-chemical and electro-metallurgical industries.

The growth in the absorbing capacity of various communities is very clearly indicated by the citations from Mr. Gaby. In the Greater Chicago District, the increase in consumption in 1923 over 1922 was over 15 per cent. The State of Illinois has an absorptive capacity of 1 e. h. p. per year for each 4 people of its population, Chicago and the surrounding territory within a radius of 150 miles for each 4.43 of population, and New York within a similar radius, for each 4.5 of population.

It should be understood that the region of Canada within 150 miles of the Long Sault Rapids is rich in water power and that comparatively few of the available sources have been developed. The Ottawa River entering the St. Lawrence River at Montreal has many available water-power sites; the St. Maurice entering the St. Lawrence at Three Rivers, 95 miles below Montreal, has much unused power and developments at Grand Mere, Shawinigan Falls, and La Gabelle. The extensive developments at Shawinigan Falls generate and transmit current for aluminum and public utilities, and grind wood pulp, with a down-hill rail haul of 21 miles to reach water navigation in the St. Lawrence. La Loutre Dam, recently constructed, creates a reservoir with a surface area of 300 sq. miles near the headwaters of the St. Maurice River and to some extent increases the low-water flow. It must be understood that the developments mentioned have the disadvantages of flashy streams, instead of the eternally even-running flow of the St. Lawrence River. The development of St. Lawrence power will flood the market and possibly degrade the values of many of these undeveloped sites.

On the United States side, it has already been demonstrated that a considerable block of power may be advantageously transmitted to New York State and to Southwestern New England. New York City is about equidistant from the Long Sault and from Niagara Falls—300 miles away. Schenectady is 160 miles from the Long Sault and 260 miles from Niagara Falls. Albany is 175 miles from the Long Sault, and Boston is 270 miles.

Prime Current

The very nature of the continuous even flow of the St. Lawrence River indicates the use of prime power for 24-hour industries operating 365 days

per year and requiring electric current at a cost not exceeding 3 mills per kw-hr. The electric furnace is the dominant consumer. Perhaps the growth in the use of electric-furnace current has not been as rapid as that of public utilities in the past; but for the future it will serve an infinite variety of purposes.

Prime current permitting 100% utilization of great manufacturing plants is worth considerably more than intermittent current. In public utilities, prime current is worth about three times as much as excess current. For public utility uses, the cost of long-distance transmission lines indicates the wholesaling of base load current to various corporations operating in the region tributary to the St. Lawrence, while peak loads of short duration may be carried by local inexpensive steam installations. In the Greater Chicago District the electric current generated by steam averages 2.23 lb. of coal per kw-hr. of output. This means a fuel cost, at $5 per ton of coal, of 11.4 mills per kw-hr. This is a public utility, with a load factor of about 50%, retailing about 60% of the energy for residential and commercial lighting and to small power users.

Canadian Policy

The energy to be generated in the Long Sault Rapids plant will be absorbed shortly after the development is completed. The remaining power of the St. Lawrence is Canadian. It will be an economic question for Canada to decide whether she will patiently await the inevitable coming of industries to her own territory with the inevitable building up of her commercial importance, or will transmit this power, with losses, to available markets largely in the United States. Questions of customs duties will enter, but the chances are that, in the end, the Mohamet of industry will be compelled to go to the Canadian mountain of power.

Niagara Water Power

The real immediate competitor of the St. Lawrence River power is Niagara River power, with a probable cost of production of less than 3 mills per kw-hr. The question is whether the great electro-chemical and electro-metallurgical industries will prefer first Niagara Falls or the vicinity of the Long Sault Rapids. Ultimately, no choice will exist; it must be Montreal.

Electric current from the Long Sault Rapids and from Niagara Falls will meet at Oswego, practically 135 miles from each development. The probable place of the interconnection of the two great hydro-electric systems will be at Syracuse, already reached by high-tension transmission lines from Niagara Falls, and substantially 150 miles distant from each of the developments.

Present Developments

The water power installations on the Niagara River aggregate about 570 000 e. h. p. for the American side and 700 000 e. h. p. for the Canadian side of the river. Only one of the present installations utilizes the water of the Niagara River under a head of over 300 ft. The total fall between Lake Erie and

Lake Ontario is 326 ft. Between Lake Erie elevation at the Buffalo Lighthouse and the head of the Rapids approaching the cataracts at Niagara Falls, the difference in elevation is about 10 ft. This leaves a gross head of 316 ft., utilizable, with some slope losses, for hydro-electric development. (See Plate VI.) The new Chippawa-Queenston plant of the Hydro-Electric Commission of Ontario operates under a head of 304 ft. The head utilized by the Niagara Falls Power Company in its major installations on the New York side of the river is 212 ft. The effective head utilized by the Ontario plant of the Hydro-Electric Commission, taking water from near the head of the Rapids and discharging, with penstock losses, into the Maid-of-Mist Pool in the Gorge, is about 170 ft. The three other installations, one on the New York side and two on the Canadian side of the river, have effective heads of from 130 to 150 ft. These three plants are doubtless marked for relegation to peak-load and standby purposes, when new plants are built, to use efficiently the limited volume of flow.

Treaty

The volume of flow for hydro-electric uses at Niagara Falls is limited, by the Boundary Waters Treaty of 1910, to 20 000 sec-ft. for the United States and 36 000 sec-ft. for Canada. The limitations imposed contemplate the preservation of the scenic grandeur of Niagara Falls. The combined water use of all present installations would exceed the limitations imposed by this Treaty. The use of water, therefore, in the more efficient plants must compel the stopping of the wheels in the less efficient plants.

Assuming for all developments at Niagara Falls an output of 29 e. h. p. for each cubic foot of water permissible under the Treaty of 1910 (56 000 sec-ft.), the total power output would be over 1 600 000 e. h. p. The actual output from the use of this volume of water is about 1 000 000 e. h. p., indicating that without reforming the treaty in quantity of water, but extending it to include diversions from the Maid-of-Mist Pool, an additional 600 000 e. h. p. will become available. This is 75% of the allotment of the United States at the Long Sault Rapids.

Future Power

It will be practicable to utilize, at Niagara Falls and in the Niagara Peninsula, after regulating works have been constructed, about 40 000 cu. ft. per sec. more water than was used in 1924 for all purposes of water power and navigation. Should this additional diversion become permissible under the terms of a new treaty with Great Britain, 1 160 000 e. h. p. more will become available. The efficient use of the 56 000 sec-ft. permissible, added to the proposed diversion, will make the ultimate volume about 2 800 000 e. h. p., which is 1 800 000 more than is now (1924) in use. As before stated, Niagara power, under a reformed treaty, is the greatest competitor of St. Lawrence power. The writer in a report on the preservation of Niagara Falls in 1908,* stated, "* * * the possibilities of continued and extended use of power at the Falls are conditioned upon the construction of regulating works in the Niagara River to avoid the wasteful outflow of the water of Lake Erie."

* Senate Doc. No. 105, 62d Cong., 1st Session, p. 75.

Power Uses

Before passing to the matter of the conservation and control of the waters of the Great Lakes for water-power betterment on the Niagara and St. Lawrence Rivers, it will be illuminating to note some uses of power at Niagara Falls: Abrasives, including carborundum; refractories, including fused alumina, high temperature electric furnaces, crucibles and pyrometer tubes; silicon carbide; firesand, electrically sintered magnesia; aluminum and its alloys in an infinite variety of forms; ferro-alloys, including ferro-silicon, ferro-chromium, ferro-tungsten, ferro-molybdenum and ferro-titanium; sodium bichromate and potassium bichromate; sodium; chrome alum, chromium sulfate, chromic acid, all three used in tanning leather; hydrochloric acid; carbon tetrachloride, sulfur chloride, caustic potash, caustic soda, liquid chlorine, bleaching powder, graphite, carbon electrodes, sodium chlorate, potassium perchlorate, barium chlorate, hydrogenated oils, titanium aluminum bronze, copper calcium alloy, potassium chlorate, formaldehyde; cyanamid, used as a fertilizer or for ammonia and nitric acid. It will be observed that these are all electric-furnace products. In addition, are the grinding of pulp wood and the making of paper with boilers electrically steamed for heating purposes, the grinding of wheat and grain, and an infinite number of small power uses.

Niagara Water Supply

The Niagara River, like the St. Lawrence River, has suffered seasons and years of low flow, because Nature appears to have little interest in the maintenance of the lakes for purposes of navigation, or the maintenance of an even flow in its rivers for water-power uses. The natural unrestrained outflow of the Great Lakes has served the elemental purpose of transferring from the basin of the Great Lakes to the ocean the eternally recurring rainfall surplus. For navigation and water-power uses, guidance by engineers is essential.

The water supply outflowing in a state of Nature through the Niagara River is shown in Table 4.

In Table 4, the outflow since 1900 in the Drainage Canal at Chicago is counted as outflowing in the Niagara River. The volumes for navigation passing through the Welland and Erie Canals, and the volume passing through the Welland Canal for water-power uses, are likewise counted as part of the water supply shown.

Comparing Table 4 with Table 3, showing the water supply of the St. Lawrence River, it will be observed that the earlier 30 years and the later 34 years show very little change in supply, demonstrating that the water supply of the Great Lakes is not failing. The indication is that changes at the Galops Rapids have modified the St. Lawrence outflow. Based on this comparison of the supply of the two streams, the water supply for the St. Lawrence River has been adjusted by subtracting an obviously excessive quantity. It will be observed that the local supply of Lake Ontario for the mean of 64 years

amounts to about 32 000 cu. ft. per sec. more than the Niagara supply. The yield for Lake Ontario is somewhat in excess of its percentage drainage basin area.

TABLE 4.—Niagara Water Supply and Yield of Great Lakes, Excepting Ontario.

Periods.	Total supply, in second-feet.	Yield per square mile of drainage basin, in second-feet.
1860–1864	202 000	0.793
1865–1869	213 000	0.836
1870–1874	202 000	0.793
1875–1879	206 000	0.809
1880–1884	234 000	0.919
1885–1889	210 000	0.786
Mean of 30 years	211 200	0.830
1891–1895	186 000	0.730

1901–1905	210 000	0.824
1906–1910	198 000	0.777
1911–1915	218 000	0.856
1916–1920	215 000	0.844
1921–1924	175 000	0.687
Mean of 34 years	202 600	0.796
Mean of 64 years	206 700	0.811

Gain by Regulation

The result of utilizing all the Great Lakes as reservoirs shows a gain of 20 000 sec-ft. of dependable flow for the Niagara River. After deducting 10 000 cu. ft. per sec. for the Chicago diversion, the mean supply for a period of 64 years is 196 700 cu. ft. per sec. With the proper limitations in the pull-down of Lakes Superior, Michigan-Huron, and Erie, the volume of prime outflow may be taken as 190 000 cu. ft. per sec. If 100 000 cu. ft. per sec. be assigned to water power and navigation uses in the Niagara River and in the Niagara Peninsula, 90 000 cu. ft. per sec. remains available to perpetuate the scenic grandeur of Niagara Falls.

Preservation of Niagara Falls

Hydro-electric engineers do not always accept graciously the thought that a great volume of water which might serve industry, be devoted to the maintenance of a great spectacle. Perhaps the fate of the cataracts may be forecast by saying that when the poverty of the nation compels the conversion of the National Parks, including vast timbered tracts, to commercial uses, and when money is no longer spent for city parks and playgrounds, and architectural refinements in buildings are omitted, and the art institutes are closed—then all the water of the Niagara, as far as practicable, may be de-

voted to hydro-electric uses. For the present, not less than 90 000 cu. ft. per sec. of water must be reserved for the preservation of the scenic grandeur of Niagara Falls.

Value of Added Water

The value of 20 000 sec-ft. of dependable water added to the Niagara River as a result of Great Lakes regulation may be arbitrarily assigned at $58 000 000. It should be stated here that the value of water power at Niagara Falls or on the St. Lawrence is not the difference in cost between electric energy generated by steam or water for the reason that industries requiring cheap power would seek other water powers or use steam installations near the pit mouth. The market for the Niagara and St. Lawrence is created by the cheapness of the power. It should be observed also that there is no vital concern in regard to the saving of bituminous coal, because at the present rate of consumption the visible supply in the United States will last for more than 5 000 years.

Great Lakes Regulation

The writer has repeatedly referred to Great Lakes regulation. It is desirable to visualize clearly the Great Lakes System. It is made up of two immense reservoirs, Superior and Michigan-Huron, with little or no water-power development in the outflowing rivers, St. Marys and St. Clair. The Niagara River, with its great descent of 326 ft., has immediately above it the lesser reservoir of Erie as a forebay; and likewise the St. Lawrence River with its power drop of 200 ft. has above it the lesser reservoir of Ontario as a forebay. (See Fig. 7.)

The writer in 1923 had a part in the development of hydro-electric power on the western slope of the Sierras in the Eldorado Region of California. Terms used there are applied to the Great Lakes for clearer visualization. Near the crest of the Sierras, storage reservoirs conserve the rainfall and the melted snow of the wet season for use during the dry season. Reservoir water passes through ditches, canals, and flumes, to a smaller reservoir, called a forebay, having a supply good for 12 to 120 hours, immediately above the 1 800-ft. power drop. The forebay is used for peak-load operation and for emergency supply in case of interruption in ditch service. The water of the reservoirs and of the forebay is expended on a well planned budget system. On the Great Lakes, Superior and Michigan-Huron are the reservoirs in the High Sierras and Erie and Ontario are the forebays just above the power drops. Erie will serve magnificently as a forebay for Niagara power and will permit variations of flow in the Niagara River during the different hours of the day. Any interference with navigation in the Niagara River will be trivial compared to the vast economic gain from intermittent river flow. In the same manner, Ontario will serve magnificently as a forebay for St. Lawrence power, provided the developments in the St. Lawrence are made so as to constitute an uninterrupted series of slack-water pools.

Ontario Regulation

Beginning with Lake Ontario, it has already been stated that regulating works are a part of the project recommended by the International Joint Commission. The detail of these works is immaterial in the present discussion. The principles of budget outflow alone need consideration.

The writer suggests that Lake Ontario be regulated with a pull-down not much more than 1 ft., aiming at Elevation 247.0 at the beginning of each year. This will be good for navigation. No danger of high water will exist in Lake Ontario, because any large local supply such as occurred in the spring months of 1912 and 1913, will be offset by checked flow in the Niagara and St. Clair Rivers, or by the discharge of an excess volume to the sea through the St. Lawrence River.

It is desirable for purposes of control to increase the channel capacity of the St. Lawrence River to the extent of 50 000 cu. ft. per sec. This will mean no more dredging than will be required for the utilization of the highest head without too great slope losses, and for the efficient solution of the frazil ice problem. The volume of flow for which all artificial works should be constructed may be about 300 000 cu. ft. per sec.

It should be accentuated that the St. Lawrence will have no floods—because the volume of flow will be controlled by regulating works—and that the water is crystalline, carrying no sediment and little trash. An exception to this last statement is the Ottawa River water entering Lake St. Louis above the Lachine Rapids.

There will never be any deficient flow in the St. Lawrence River because increased channel capacities and maintained Lake Ontario levels will care for the tilting up of Lake Ontario and the level drop at the head of the Galops Rapids. With an increased flow capacity of 50 000 cu. ft. per sec. over the flow in a state of Nature, a volume of 220 000 sec-ft. may be passed down the St. Lawrence when the gauge at the head of the Galops Rapids reads 242.2, which is 2 ft. below the low-water winter level. It is not anticipated that large peak-load demands will be made on the various hydro-electric plants on the St. Lawrence River, but provision for some peak-load use is desirable.

In a report on the regulation of the St. Lawrence River, in 1919, the writer suggested works at the head of the American channel of the Galops Rapids with budgeted outflow for storage and navigational betterment.

Erie Regulation

In the report of the Board of Engineers on Deep Waterways, 1900, regulating works were recommended for the head of the Niagara River (see Plate VII), and the works themselves were designed under the direction of the late Mr. Alfred Noble. The scheme as a whole is not of great interest now, as the works were designed to serve navigation alone, the growth of hydro-electric development not being anticipated. The plans show sluices with clear openings of 80 ft. controlled by counterweighted Stoney gates of massive design. For present conditions, it is probable that the submerged weir section should be superseded by sluiceway sections so as to secure the highest flow capacity

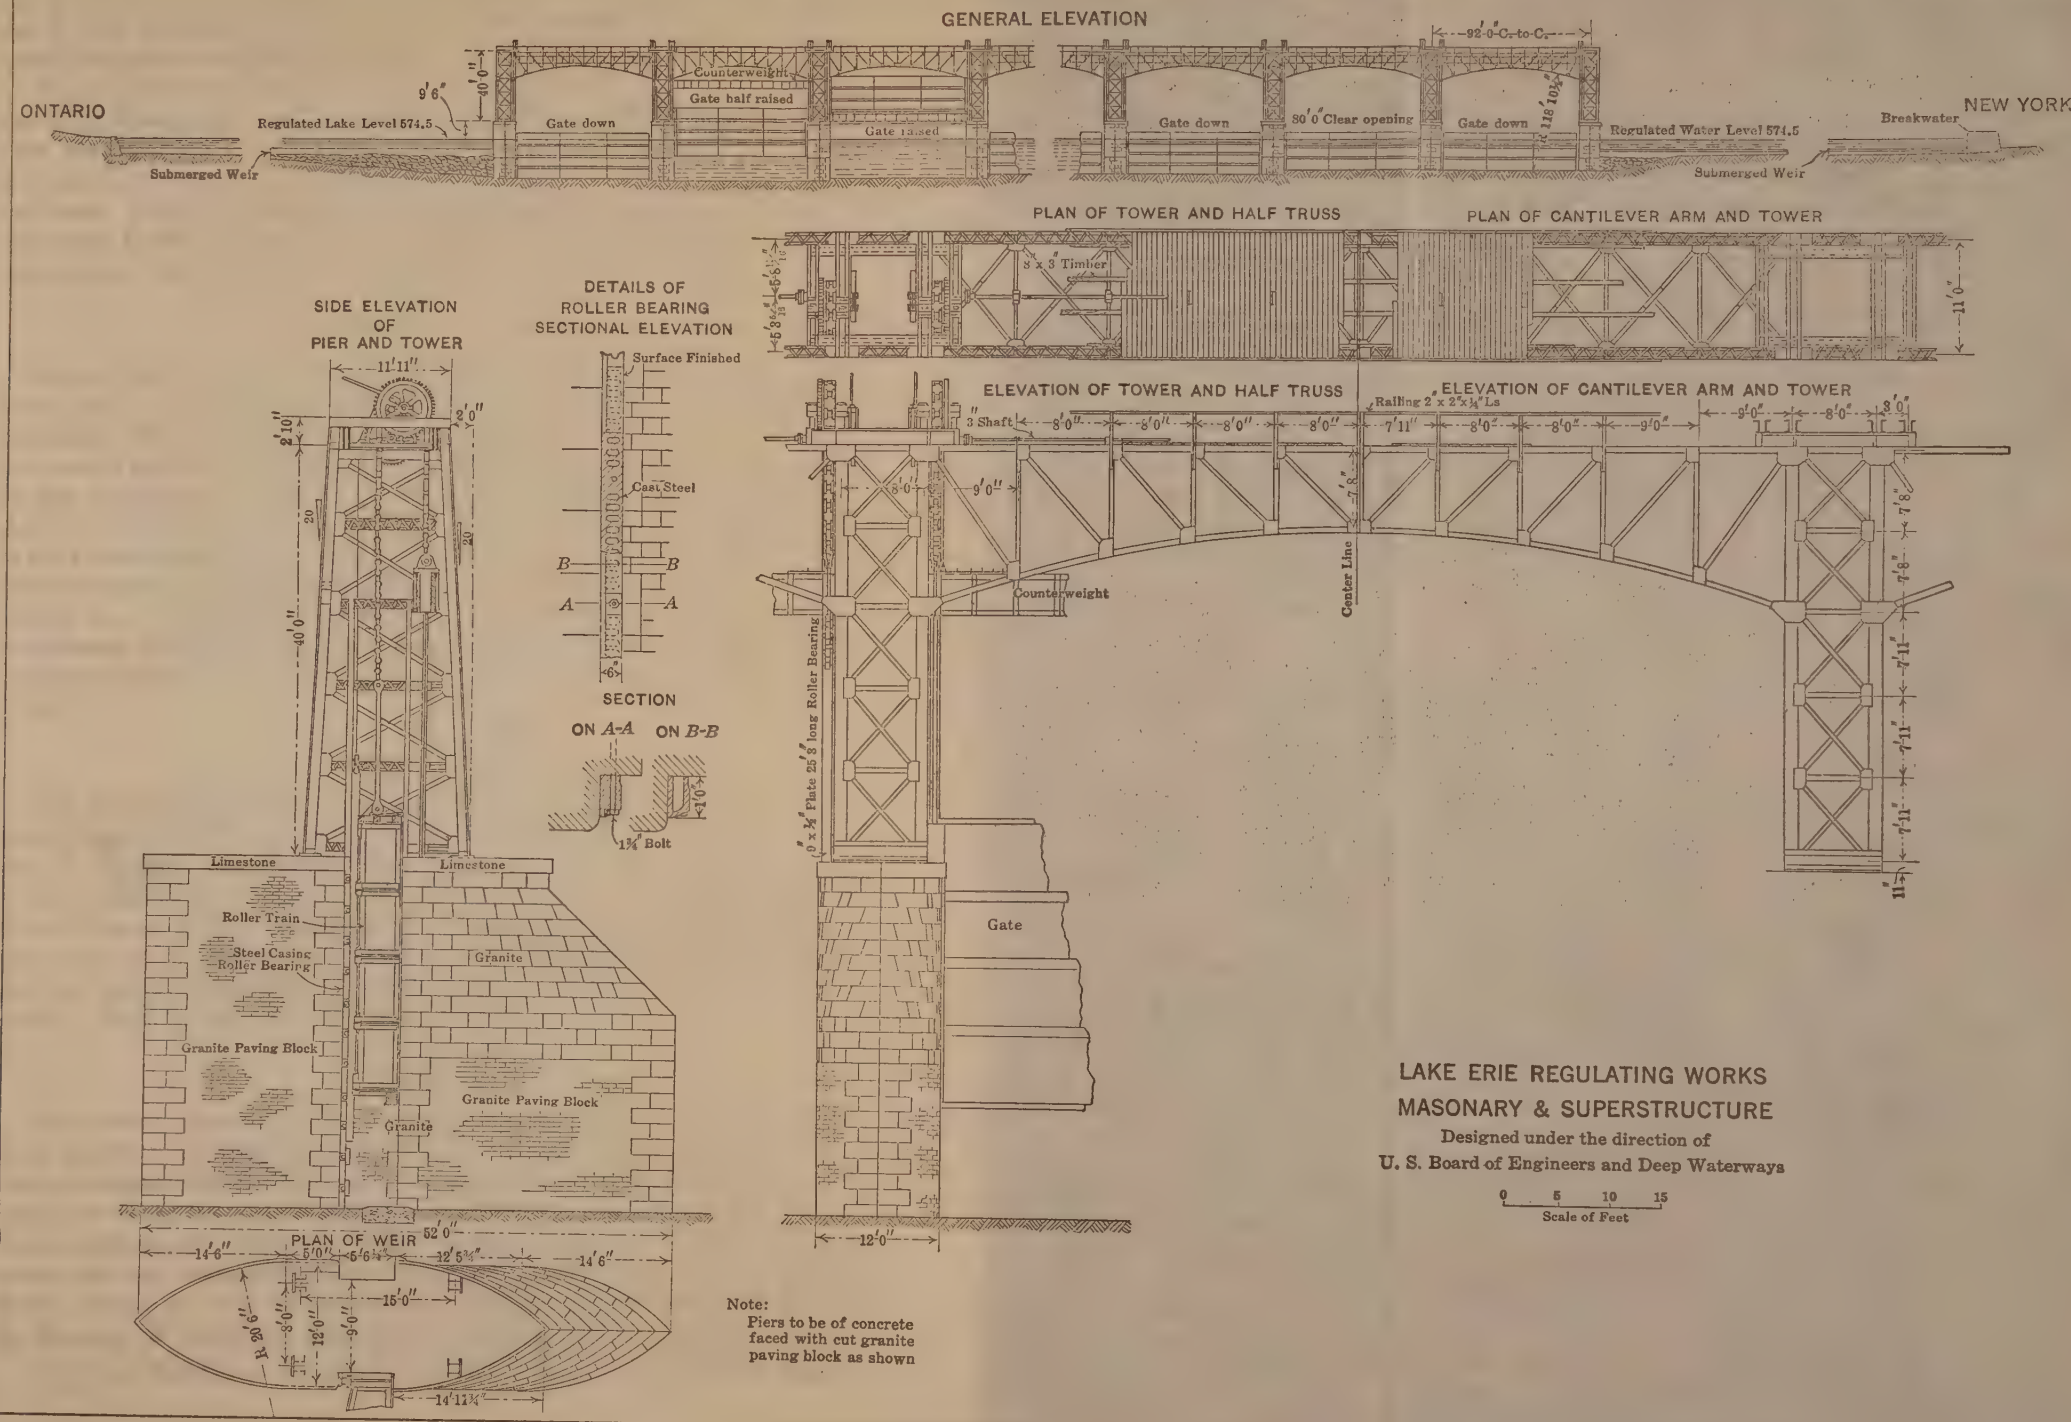
FIG. 8.



Note:
Piers to be of concrete faced with cut granite paving block as shown

and to avoid possible blocking by ice. The writer's suggestion is shown in Fig. 8. The minimum continuous flow is shown through an open pass, under normal conditions navigable down stream by small boats.

The aim of the regulation of Lake Erie would be Elevation 573.0 at the beginning of each year, with a possible cresting elevation of 573.8 ft., and a mean elevation through the season of navigation of 573.5 ft. These values in 1 year out of 5 years might be lessened about 1 ft. by emergency storage pull-down. Lake Erie like Lake Ontario will be safeguarded against unduly high water by the checking of the St. Clair River flow, or by sending excess quantities to Lake Ontario and through the St. Lawrence to the sea.

Ice in the Niagara River

The ice problem at the head of the Niagara River and violent storm conditions, with waves battering against the regulating works, need careful consideration. The writer suggests that ice should preferably rot in Lake Erie, as it rots at the head of the St. Marys and in the St. Lawrence, with no heavy ice flow in the rivers. The climatic influence on Buffalo of holding the ice above the head of the river, while it honeycombs, breaks up, and melts, would, in the writer's judgment, be negligible. The temperature of the surface water, with melting ice, will be little different from the surface temperature in April, without ice. It is certain that breakwaters enclosing the head of the river, as indicated in Fig. 8, will solve the question of the storm battering of the regulation works and, at the same time, will eliminate largely the congestion of ice.

Recommended Works

The Board of Engineers for Rivers and Harbors, U. S. Army, in a report dated August 24, 1920, and signed by Brig.-Gen. H. Taylor, U. S. A., M. Am. Soc. C. E., now (1924) Major General, Chief of Engineers, U. S. Army, has recommended the immediate construction of regulating works at the head of the Niagara River, estimated to cost $8 000 000, utilizing substantially the site chosen by Alfred Noble in 1900. The recommendations of the Board include channel enlargements to provide for a flow of from 300 000 to 400 000 sec-ft. to flush ice through the Rapids Section.*

Other Works

The writer's report of 1919 suggested a "daring" type of removable gates to be placed in the narrowest river section, 1½ miles down stream from the site now contemplated. These works had in mind the definite betterment of Lake Erie levels, and, by back-water reflection, the levels of the intervening rivers and Lakes St. Clair and Michigan-Huron. The writer is not now concerned with the mechanism which accomplishes flexible control of the outflow of the various rivers in the Great Lakes System. A clear comprehension of the function of regulating works is first essential and that already exists in

* Report on Diversion of Water from the Great Lakes and Niagara River, Washington, D. C., 1921.

the minds of the members of the Corps of Engineers, including Colonel Wooten and General Taylor. It is probable that the narrow section of the river—1 800 ft. wide—selected by the writer in 1919, will prove to be the best location and disappearing works a better type than Stoney sluices.

It must be understood that other recommendations have been made for the betterment of Lake Erie levels, mostly for the purpose of offsetting the lowering of 5½ in. due to a diversion of 10 000 ft. per sec. at Chicago. It is not desirable to examine the merits of the various suggestions. A comprehensive grasp of the vital principle of river control eliminates the use of throttling works which lie dead and inert in the river bottom or immovably constrict the river width. The vital principle of river control, for the purposes of navigation and water power, means enlarged outflow channels for the rivers of the Great Lakes to the extent of 50 000 cu. ft. per sec. over the natural outflow capacity; and it means manual control of the gates permitting augmented outflow or throttled outflow. These principles were stated definitely in the writer's report of 1919 on the regulation of the Niagara and St. Lawrence Rivers, and are re-affirmed here. Regulating works refer to works manually operated for elastic control; compensating works refer to inert submerged weirs or wing dams.

Intermittent Flow

In addition to the control of Niagara River flow for navigation and water power, is the problem of reasonable fullness in the cataracts and rapids during a portion at least of each day from May to October. The writer proposes for the cataracts a daylight volume of 150 000 sec-ft. during the months mentioned. While this large natural flow goes over the cataracts, water-power uses will be cared for by mill-pond water accumulated in the Erie forebay during 16 hours of diminished cataract and rapids flow. This may mean a river flow of 250 000 sec-ft. for 8 hours, and of 160 000 sec-ft. for 16 hours per day.

It is probable that it will be economical to build control gates at the head of the rapids above the cataracts to maintain a higher level in the Chippewa-Grass Island Pool. This will give greater depths in the water-power canals, with a gain in effective head, and also deeper navigable channels during the periods of lessened flow. These gates will serve also to re-distribute the flow over the crest of the Horseshoe Falls, lessening destructive action at the apex, and increasing depths at the extremities of the crest line. Re-distribution of the flow in the Horseshoe Falls was recommended in the writer's report of 1908, already referred to.

It should be observed lest it appear that this discussion is far afield from the St. Lawrence Waterway to the Sea that the regulating works recommended in 1900 were a part of all deep waterways to the sea, including that of the St. Lawrence to the foot of Lake St. Francis and thence through Lake Champlain to the Hudson River and New York. The maintenance of navigable depths in the lakes and rivers and the best utilization of the water supply of the Great Lakes are dominant elements in the St. Lawrence Waterway to the Sea.

Michigan-Huron Regulating Works

The general layout of regulating works at the head of the St. Clair River, to improve navigable depths in Lake Michigan-Huron and in St. Marys River to the foot of the rapids, including better depths over the lower breast walls of the ship locks at Sault Ste. Marie, is shown in Fig. 5; and these works, with the appurtenant navigable passes, have already been briefly described. The economic desirability and the physical practicability of the regulation of these immense lakes are certain. The same principles apply as in the case of the St. Lawrence and Niagara Rivers, that additional outflow capacity is desirable and that the regulating works shall give elastic manual control. (See Fig. 5 and page 506.)

Over-Emphasizing Minor Losses

For the past 25 years, during the season of navigation, Lakes Michigan-Huron have been from 18 to 40 in. lower than desirable. Since the opening of the canal of the Sanitary District of Chicago in January, 1900, however, more concern has been felt for the loss of level, increasing during the period from 2 in. to 5 in., than for the large degradation of levels coming from other causes, and engineers have given their attention to the reclamation of the 5 in. rather than to the larger needs. It is obvious that the lesser loss could be compensated by contraction works in the form of submerged weirs or wing dams. A Board of United States Engineers reported in 1914 on a series of submerged weirs in the St. Clair River to restore 6 in. The writer proposed in 1919 to raise Lakes Michigan-Huron, as did the Board of Engineers on Deep Waterways in 1900, by back-water coming from a super-elevation of Lake Erie. The International Waterways Commission, 1910, gave consideration to the regulation of Lakes Michigan-Huron, but reached a conclusion that the natural regulation of the lakes was so perfect that it could not be improved on by the works of man.*

Mr. Grunsky's Forecast

"The Low Stage of Lakes Huron and Michigan" has been discussed in a paper† by C. E. Grunsky, Past-President, Am. Soc. C. E. Speaking of the increased elevation of Lakes Michigan-Huron through back-water from the super-elevation of Lake Erie, Mr. Grunsky states:‡

"It is possible, moreover, to go a step farther and to provide works for the throttling of the waterway, or for the complete control of flow, within fixed limits, of the St. Clair River. The stage of Lakes Huron and Michigan could then be brought under adequate control, and the lake stage could be maintained at all times as high as required by navigation interests.

"That regulating works will sooner or later be constructed, in the rivers draining the several lakes, of such a character that the elevation of the lakes under proper management cannot fall below predetermined minima, is reasonably certain. It follows, therefore, in view of the benefit that will be derived from the use of Lake Superior as a storage basin, and of the control

* Report of the International Waterways Comm. on the Regulation of Lake Erie, 1910.
† *Transactions*, Am. Soc. C. E., Vol. LXIII (June, 1909), p. 31.
‡ *Loc. cit.*, pp. 46–47.

of water surface that will result from works below Lake Huron, that navigation interests will be but temporarily, if at all, affected by a diversion of water at Chicago, or elsewhere within reasonable limits as to amount, and that any deleterious effect will not continue beyond the time when the water elevation of this lake and Lake Michigan will be controlled by works below Lake Huron.

"The stages of Lake Ontario and of the St. Lawrence River are questions apart from the one that has here been discussed. Enough has been said, however, to show that here, too, the less than normal stages of recent years are to be ascribed to climatic conditions, supplemented in a very slight degree only by the diversion at Chicago. The ultimate effect of the diversion of water from any of the lakes, offset by the equalizing effect of lake regulation, upon the stage of water in the St. Lawrence River is a study that will have to be made when the regulating works come under consideration."

Superior Regulation

The writer's suggestion is to regard the regulation of the lakes, not as piecemeal and individual, but as a continuous, interrelated series in which each lake serves all the others. As Lakes Superior and Michigan-Huron are treated as a unit of storage, it is well to pass immediately to the existing regulating works at the head of St. Marys River, giving manual control of the outflow of Lake Superior. The original design of these controlling works was made under the direction of the late Mr. Alfred Noble, very shortly after the design of the works at the head of the Niagara River. Sections of the works were built to compensate for water-power diversions in lateral canals, and these sections existed for a number of years as dead, inert, unoperated, compensating works, permitting diversions without unduly disturbing the level of Lake Superior. Later, water-power development on both sides of the river became the adequate reason for completing the works and operating them manually. These works now consist of a battery of sixteen sluices, each with a clear opening of 52.2 ft., with massive steel Stoney gates. In addition, there are three 33-ft. sluices in the dam of the United States power plant. These works are shown in Figs. 4 and 10. The original construction is detailed in a paper by G. F. Stickney, M. Am. Soc. C. E., entitled "The Compensating Works of the Lake Superior Power Company."* The recent works and their operation have also been described† in much detail by Mr. Louis C. Sabin.

It will be assumed that the regulating works, with the added flow in the water-power canals on each side of the river, have an excess outflow capacity of 50 000 sec-ft., or more, over that of the natural rapids. The volume of flow through the wheels, either running or blocked open, may be regarded as effective outflow capacity for the water-power plants on the St. Marys River. In considering the capacity of flood flow on flashy streams where abnormal conditions of ice or trash might prevent penstock flow, it is regarded as desirable to have other spillways of adequate capacity. For the streams of the Great Lakes, however, no comparable flood conditions exist. A brief shutdown of the power plants at Sault Ste. Marie at the time of maximum supply,

* *Transactions*, Am. Soc. C. E., Vol. LIV (June, 1905), p. 346.

† In an article in the *Military Engineer*, reprinted in the *Canadian Engineer*, March 21, 1920.

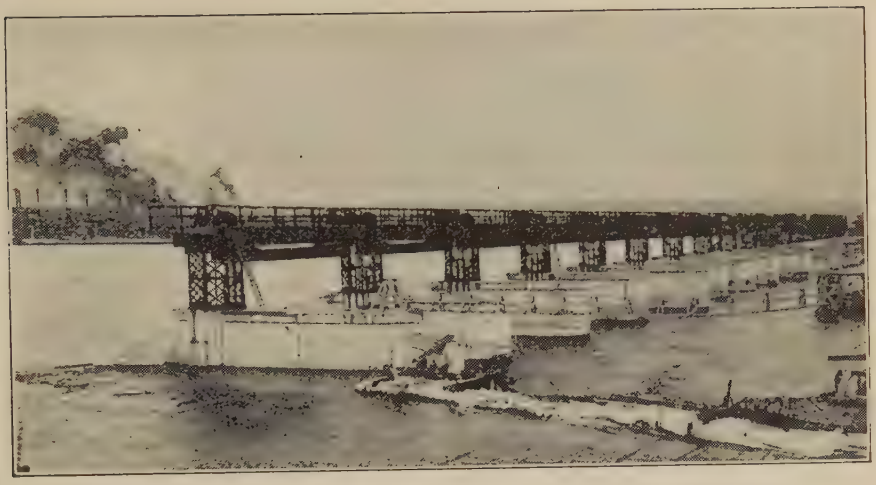


FIG. 9.—VIEW OF REGULATING WORKS IN ST. MARYS RIVER.

FIG. 10.—VIEW OF PART OF REGULATING WORKS AT SAULT STE. MARIE.

will have a negligible effect on the level of Lake Superior. On the Niagara and St. Lawrence, however, the well-being of the tandem series of plants should involve adequate spillway capacity so that lower plants may not be shut down in case of blockade in an upper plant.

It is noteworthy that no scheme of regulation to better navigable conditions by the maintenance of higher surface levels has originated with the shipping interests of the Great Lakes. With the exception of the Gut Dam at the Galops Rapids of the St. Lawrence, the compensation has always been suggested by diversions for sanitary or water-power purposes, rather than for the maintenance of levels when the supply conditions of the Great Lakes needed the throttling of the outflow toward the ocean.

The water power at Sault Ste. Marie contemplates a prime diversion of 50 000 sec-ft., with the use of 10 000 sec-ft., or more, of excess water when the Lake Superior supply warrants additional outflow. The use of this water for power purposes at Sault Ste. Marie, under a head of 20 ft., less slope losses in the canals, should amount to about 90 000 e. h. p. The actual development is somewhat less than this. The water power here, with perhaps an effective head of 18 ft., is not comparable with the great powers at Niagara with a head of over 300 ft., or with the ultimate great powers on the St. Lawrence with heads aggregating 200 ft. The release of Lake Superior water should contemplate the well-being of navigation and the lower water powers, rather than the over-accentuation of the local water powers of St. Marys River. The water power at Sault Ste. Marie, is largely used for the making of carbide, ferro-alloys, electric smelting, the grinding of wood pulp, and the making of paper.

Assuming a cost of $750 per ft. for works installed at Sault Ste. Marie, under post-war conditions, the total cost for the main river section is about $750 000. The cost on the American side was borne initially by the water power companies, but the United States is assuming the cost by the remission of water power rentals. It should be understood that at Sault Ste. Marie, under the decision in the famous Chandler-Dunbar case, all submerged lands were taken over by the Federal Government for purposes of navigation. This made the United States a water power proprietor, receiving each year as rentals for the use of the water, $2 per sec-ft. for prime water and $1 for secondary water. Here, then, exists a little subsidization of navigation by water power.

The operation of the regulating works in St. Marys River is under an International Board, the program contemplating the maintenance of Lake Superior levels between the limits of 601.5 and 604.1 ft. The program is based on the needs of Superior alone without necessary benefit to Michigan-Huron.

The final closing of the gap completing the work and placing Superior under full manual control is so recent that the value of regulation is not yet fully demonstrated. In the paper already referred to, Mr. Sabin writes:

"When the works are entirely completed the flexibility of the system will be increased, since the entire flow will be under control; the degree of regulation will not be materially improved, however, but a greater use of water for

power will be permissible. What will be accomplished, then, is the continuous use of the natural minimum flow, equal to about 75% of the mean discharge of the river, and a reduction of the fluctuation in monthly mean levels from a range of 3.8 ft. to a range of about 2.6 ft. The economic advantage of power development to the extent of some 80 000 h. p. is thus combined with improvements of navigation conditions."

Regulated Levels

Lake Superior has not been entirely immune from the low-water régime existing on the other lakes. The reason for this is the tremendous inertia of the lake, which will require a number of years of ample supply or restricted outflow to bring it up. Assuming that it is desirable to raise the surface level of Lake Superior 1 ft. over the present level, it will be necessary to throttle the outflow to the extent of over 28 000 sec-ft. for 1 year, or 14 000 sec-ft. for 2 years. At a time when the lower lakes need the water, it is not practicable to accomplish this restoration of Lake Superior level. This must await regulating works in all the Great Lakes, so that the supply may be simultaneously throttled in all.

In the scheme of regulation suggested by the writer, Lake Superior will preferably stand at about Elevation 602.5 at the beginning of each year. As the year progresses, the lake will normally rise to a cresting height of 603.3 ft. in September, and gradually drop to Elevation 602.5 by the end of the year. This is the normal cycle in a state of Nature. To what extent it will be modified under manual regulation is not yet definitely clear. The limiting cresting stage is about 604.1 ft. Between cresting at 603.3 ft. and 604.1 ft. is a depth of 0.8 ft. To fill the lake to this depth in 4 months will require an excess of roundly 85 000 sec-ft. more than the normal generous supply of these productive months. As the excess capacity of the outflow works permits a release of 50 000 sec-ft. over the release in a state of Nature, the actual rise might be held to Elevation 603.6.

Effect on Michigan-Huron

The dumping of 50 000 sec-ft. for 4 months will raise the level of Lakes Michigan-Huron, with manual control at the head of the St. Clair River, about 0.4 ft. The hazard of high water in Superior, with regulating works in operation and with 50 000 sec-ft. excess channel capacity, appears to be slight.

In case Lakes Michigan-Huron, under these circumstances, are at a stage where the addition of 0.4 ft. is undesirable, the excess volume of 50 000 sec-ft. may be simultaneously discharged through the St. Clair River to Erie, through the Niagara to Ontario, and through the St. Lawrence to the sea, without any level change in the intermediate lakes. The Superior Reservoir should be regarded as a unit with the Michigan-Huron Reservoir. When Michigan-Huron has a greater supply than it needs for its level maintenance within safe limits, the throttling of the flow of the St. Marys River will retain any desirable quantity in the Superior Reservoir. Conversely, when Michigan-Huron needs additional water, this may be secured by release from Superior.

The immediate passing of water to the sea by opening simultaneously all works to the maximum extent of 50 000 sec-ft. will dispose of the excess supply.

Storage Reservoirs

The areas of the land part of the Superior Basin and of the reservoir are shown on Fig. 7. A depth of storage of 1 ft. on Superior has a value of 28 000 sec-ft. over a period of 1 year, and the combined storage capacity of the Superior and Michigan-Huron Reservoirs, for a pull-down of 1 ft., amounts to 68 000 sec-ft. over a period of 1 year, or 20 000 sec-ft. for a period of 3.4 years. It will be noted in Table 2 that the maximum net storage release from all the Great Lakes, including the forebays of Erie and Ontario, during the years 1921 to 1923, inclusive, amounts to about 24 000 sec-ft.; and that the maximum net release required from all reservoirs and forebays in the exceptional low-supply, 4-year period, 1921-25, is 25 000 sec-ft. The storage value of the Superior and Michigan-Huron Reservoirs alone over a period of 5 years amounts to 13 600 sec-ft., while the capacity of all reservoirs and forebays for a depth of 1 ft. is nearly 17 000 sec-ft.

Michigan-Huron Supply

The outflow conditions in the St. Marys River are simple, and it is known that the average Superior supply amounts to about 80 000 sec-ft. It is known also (see Table 3) that the average supply outflowing in the Niagara River is 205 000 sec-ft. The average supply coming from Lakes Michigan-Huron and Erie is, therefore, 125 000 sec-ft. If it should be assumed arbitrarily that the Erie supply is 20 000 sec-ft., then Michigan-Huron shows an average supply of 105 000 sec-ft. The average outflow of the St. Clair River is then about 185 000 sec-ft. This outflow value is somewhat startling, because the outflow of the St. Clair, when Lake Huron is at its average stage of 581.1, is 205 000 sec-ft. There is, therefore, a discrepancy of 20 000 sec-ft. This is attributable to the fact that during the months of January to April, inclusive, the outflow of the St. Clair River under ice conditions is restricted to perhaps 150 000 sec-ft. In considering manual regulation of Michigan-Huron, the condition during the ice months mentioned must be given the fullest consideration.

St. Clair River Winter Flow

The small winter discharge capacity of the St. Clair River, suggested as perhaps 150 000 sec-ft., may doubtless be increased, if desirable, by channel improvements, more particularly in the delta section of the river. The hydraulic explanation of this small winter outflow is simple. In the open season the river utilizes 5.5 ft. of head as potential to meet the various energy expenditures in its 40 miles of channel. When winter comes, it finds itself flowing in part under an ice cover with diminished cross-sectional area. The various resistances must then be increased requiring a greater fall than 5.5 ft. The result, therefore, with a fixed head of 5.5 ft., must inevi-

tably be lessened volume of flow. Notwithstanding this lessened winter flow of the St. Clair River—somewhat augmented now by channel improvements—the Niagara River continues its outflow in ample volume, depending on Erie storage and local supply to supplement the lessened St. Clair River inflow; and the St. Lawrence River with its local supply, Ontario storage, and ice retardation, continues in ample flow.

Michigan-Huron Regulation

The suggested regulating works at the head of the St. Clair River for manual control, and the necessary vessel passes are shown in Fig. 5. The foundation for all works is boulder clay. The regulating works indicated, contemplate 3 000 ft. of 80-ft. sluices with massive Stoney gates, similar to those proposed by the Board of Engineers on Deep Waterways in 1900 for the head of the Niagara River. (See Plate VII.) Based on the estimate made by the Board of Engineers for the Niagara River, the cost of the regulating works will be about $1 000 per lin. ft., or about $3 000 000. In addition will be the cost of lateral pier work for the east section, $500 000; and 1 700 ft. of sluice dam west of the expansion basin walls, costing perhaps $500 000. The total cost of regulating works is about $4 000 000. The three navigable passes and the two concrete expansion basins, will cost about $5 000 000. Breakwater protection—not shown in Fig. 5—above the uppermost pass will cost about $1 000 000. The total cost of all works at the head of the St. Clair River will be about $10 000 000. No provision is made for excess outflow capacity other than that due to the superelevation of the water surface of Lake Huron, and that due to enlarged navigable channels throughout the St. Clair River. No specific item of cost is assigned for dredge work within the expansion basin, and forming part of the large project of channel excavation required for 25 and 26-ft. navigation. As the vessel passes are no-stop works, no costs of operation similar to the costs at the ship locks at Sault Ste. Marie are involved. The ultimate capitalized value of these works to navigation and water power will be not less than $70 000 000.

The regulation of Michigan-Huron contemplates an elevation at the first of the year of 582.0 ft., with a cresting elevation of 583.0 ft. These elevations are subject to an emergency pull-down of 1 ft. for the use of storage for lake-level preservation in Lakes Erie and Ontario and the maintenance of uniform flow in the Niagara and St. Lawrence Rivers for water-power purposes.

The inertia of this vast reservoir safeguards riparians against high water. With the Michigan-Huron Reservoir at Elevation 582.2, at the beginning of April of a given year, it will require an excess supply from its own water-shed of 120 000 sec-ft., continuing for 4 months, to raise the lake to Elevation 583.2, and this is still 0.3 ft. below the cresting elevation in July, 1876, and June, 1886, and 1.5 ft. below the high water of 1838. Should an excess flow capacity in the St. Clair River of 50 000 sec-ft. be invoked to check this rise, the elevation in the July cresting in the illustrative case will be 582.8 ft. instead of 583.2 ft. The normal rise, with St. Marys River inflow without control, is 0.7 ft. between the first of April and the last of July. After July, the level of the Michigan-Huron Reservoir almost invariably drops.

The geographical regions embraced in the water-sheds of the Superior and Michigan-Huron Reservoirs are so extended that the diversity element of supply enters to a considerable extent. When the Superior Reservoir is receiving an exceptional supply, it is by no means certain that the Michigan-Huron Reservoir in its own basin is receiving a comparably large supply. The diversity element is more conspicuous still, in the regional differences between Superior and Erie and Ontario.

Restoration

On January 1, 1925, Lakes Michigan-Huron were 3½ ft. below the desirable regulated stage of 582.0 ft. To restore these lakes to this elevation will require a throttling of the outflow to the extent of 28 000 sec-ft. for a period of 5 years. The probability is small of level restoration without artificially throttling the flow of the St. Clair River. Reference to Table 4 indicates that the probability of a net excess volume of 20 000 sec-ft. for a 5-year period is 1 in 12. In the period, 1880-84, the net excess was at the rate of 19 000 sec-ft. The restoration of the Superior and Michigan-Huron Reservoirs, therefore, must be accomplished by lessened flow in the St. Clair, Niagara, and St. Lawrence Rivers over a period of from 5 to 10 years. Regulation in the Niagara River by works built simultaneously with regulating works above the head of the St. Clair River should precede the throttling of the outflow of Lake Huron for level restoration. This throttling should be accomplished in as large a measure as practicable during the non-navigation period between mid-December and mid-April.

Instantaneous Water Delivery

The infirmity of the natural operation of the Superior and Michigan-Huron Reservoirs is in the fact that it is impossible to deliver water to Lakes Erie and Ontario without the lapse of a long time interval. Should the St. Lawrence River need additional water at a time when Lake Superior is filled to the limit of its storage capacity, it would take 5 years to transmit this water in some such volume as 20 000 sec-ft. to the head of the St. Lawrence River. The Superior water released by the regulating works at Sault Ste. Marie must first raise the level of Lakes Michigan-Huron practically 1 ft. before the St. Clair River is able to discharge the 20 000 sec-ft. inflowing from St. Marys River, and Lake Erie likewise must rise nearly 1 ft. before it, in turn, will be able to transmit the water to Lake Ontario.

The outstanding value of co-ordinated regulation from the point of view of lake-level maintenance in Lakes Erie and Ontario and water-power use in the Niagara and St. Lawrence Rivers, arises from the fact that storage in the Superior Reservoir may be made immediately available, without a day's loss of time, for use in the St. Lawrence River. The procedure is as follows:

The St. Lawrence River needs 20 000 sec-ft. additional water. Instantaneously release 20 000 sec-ft. through the St. Marys River, the St. Clair River, the Niagara River, and the St. Lawrence River. The St. Lawrence then uses immediately the needed 20 000 sec-ft., without any change in the surface elevations of Lakes Michigan-Huron, Erie, or Ontario. This pro-

cedure is like cashing at Ogdensburg a draft on funds at Duluth. The ideal development at the St. Lawrence River in a series of four slack-water pools corresponds very closely with the geological layout of the four slack-water pools of the Great Lakes, and the transmission of water for peak-load use through the St. Lawrence from pool to pool will follow the instantaneous procedure described. Having in mind the fact that at present it takes a number of years to transmit available storage water from the Superior Reservoir to the head of the Niagara River, the tremendous economic gain in water use in the instantaneous transmission proposed by the writer is obvious.

At the Annual Convention of the Society in July, 1898, a paper by the late Brig. Gen. Hiram M. Chittenden, U. S. A. (*Retired*), M. Am. Soc. C. E., then Captain, Corps of Engineers, U. S. A., entitled "Reservoir System of the Great Lakes of the St. Lawrence Basin",* with a "Mathematical Analysis of the Influence of Reservoirs upon Stream-Flow", by the late James A. Seddon, M. Am. Soc. C. E., was presented by Mr. Seddon. In this paper the lag in time between the release of water from Lake Superior and its outflow in the St. Lawrence River was fully discussed.

Erie Regulating Works

The regulating works at the head of the Niagara River, with breakwater protection, as shown in Fig. 8, might cost approximately as follows: Sluices with Stoney gates, 4 000 lin. ft., $4 000 000; breakwaters, 3 miles in length, $3 000 000; channel enlargements for excess capacity flow, $3 000 000; total, $10 000 000. It will be understood that these estimates are roughly approximate. The Black Rock ship lock recommended by the Board of Engineers on Deep Waterways in 1900, to by-pass works at the head of the Niagara River, has already been built.

Expedients

Doubtless preliminary inexpensive measures may be used to restore, in part, the levels of Lakes Michigan-Huron. Submerged weirs in the St. Clair River and regulating works with gates in the Niagara River, to raise Lake Erie level and by back-water reflection the level of Lakes Michigan-Huron, will restore water-level losses chargeable to the diversion of 10 000 sec-ft. at Chicago. If no further betterment of lake levels or of water supply is needed, these simple expedients will serve. The future, however, will require the adequate regulation suggested by the writer in this paper. The permanent use of submerged weirs or wing dams violates the fundamental principle of regulation, which requires excess channel capacity in the St. Clair, Niagara, and St. Lawrence Rivers.

Canals as Excess Outlets

It should be understood that all continuously flowing canals—including the Drainage Canal at Chicago, the Black River Canal at Port Huron, the Welland Canal, and the Erie and Black Rock Canals at Buffalo—count as

* *Transactions*, Am. Soc. C. E., Vol. XL (1898), p. 355.

excess capacity channels required by the ultimate effective regulation of the Great Lakes System. To the extent of the volume of flow permissible in these various canals, the enlargement cost of the natural channels of the St. Clair and Niagara Rivers will be lessened. This is clearly the case in the St. Marys River, where the entire excess capacity flow needed, has already been secured in lateral water-power canals. The use of 10 000 sec-ft. of continuous flow in the Welland Canal for water power, if that be practicable, would also lessen the cost of rock excavation in the Niagara River. To this extent, in the ultimate analysis, it is obvious that excess-flow canals serve beneficially.

Data

In order that those discussing this paper may have available full information, the following diagrams are incorporated: Plate IV is the hydrograph of the U. S. Lake Survey, showing the water surface elevations of the Great Lakes for 65 years; Fig. 11 shows curves of discharge of the St. Clair River in terms of the elevation of Lake Huron and Lake St. Clair; Fig. 12 shows the storage capacity of Lake Ontario; Fig. 13 is the curve of discharge of the Niagara River in terms of the elevations of Lake Erie height at Buffalo; Fig. 14 gives the discharge curves on the St. Lawrence River before and after the building of Gut Dam at the Galops Rapids in 1903; Fig. 15 gives a series of curves expressing relationship between discharge in the St. Lawrence River and storage in Lake Ontario; Fig. 16 shows the theoretical division of discharge between the American and Canadian channels at the Galops Rapids of the St. Lawrence River; and Plate VIII shows the detail of discharge measurements in the Niagara River, giving some indication of the precision of measurements.

Financing the Work

When the time comes to adjust between the United States and Canada the cost of the various constructions of the St. Lawrence Waterway to the Sea, the full length from Duluth, Port Arthur, and Chicago, to the foot of the canalized sections of the St. Lawrence River below Montreal, must be taken into consideration.

Should a flow of 10 000 sec-ft. be utilized for water-power purposes in the Welland Canal, securing perhaps 250 000 e. h. p., rentals might be charged for the delivered water, and the Welland Canal would then be subsidized, in part, by water power. It is permissible under the Federal Water Power Act to assess money costs and charges for operation, maintenance, and depreciation of head-waters improvements against the water powers benefited, which might include those at Niagara Falls. The Act expressly states that a charge may be made by the United States for head-waters improvements to be paid by licensees. An administrative fee of 25 cents per h. p. is now paid by the Niagara Falls Power Company. This must amount to nearly $100 000 per year. On the Canadian side, rentals are charged for the use of the water, ranging from 50 cents to $1.00 per e. h. p.-year. The writer is not informed as to whether or not this includes all water power on the Canadian side at

Niagara Falls. After the full development of 2 800 000 e. h. p. at Niagara Falls, an assessment of 10 cents per e. h. p.-year would bring in an annual return of $280 000, which capitalized at 5% is $5 600 000. Should St. Lawrence River water power ultimately pay a similar fee for head-waters improvements, the annual return there would be over $400 000 per year, with a capitalized value of $8 000 000. As navigation interests are large beneficiaries of the head-waters improvements suggested, the charge of 10 cents per e. h. p.-year against water power appears to be sufficient. The Sanitary District of Chicago has already offered to pay over $2 000 000 toward works for lake-level restoration.

International

The international aspect of the St. Lawrence Waterway to the Sea, with the various engineering works involved, needs careful consideration. Regulating works in St. Marys River, at the head of the St. Clair and Niagara and in the St. Lawrence, bestride the boundary line and modify the natural outflow of the rivers on both sides of the boundary and the natural levels of the lakes above them. The real beginnings of regulating works in St. Marys River were on the Canadian side, and the one real compensating work which has benefited lake levels, is the Gut Dam at the Galops Rapids of the St. Lawrence River, built by the Canadians with the acquiescence of the United States.

The planning and building of works to restore and improve the levels of Lakes Superior, Michigan-Huron, Erie, and Ontario and the connecting rivers, should be carried forward under a comprehensive plan, satisfactory to all parties at interest.

It should be understood that under the treaty between Great Britain and the United States of 1871, all Canadian channels, including the Welland and Laurentian Canals and the St. Lawrence River to the Atlantic Ocean, were opened forever to vessels of the United States on the same terms as to Canadian vessels; and all American channels and canals, including the locks at Sault Ste. Marie, were opened on equal terms to Canadian vessels. American vessels have long utilized Canadian waterways in the Welland and on the St. Lawrence and Canadian vessels have long used the improved waterways of Lakes Superior, Michigan-Huron, and Erie, and the connecting rivers, St. Marys, St. Clair, and Detroit. As a matter of fact, vessel tracks are no respecters of the International Boundary line, following for the most part deep water and least distance.

Delay

Probably the reason for a delay of a quarter of a century in building works at the head of the Niagara River, is the terror in the minds of laymen lest any interference with these tremendous reservoirs may lead to disaster to property on the shores of the lakes. Assurance as to the exact limit of high lake levels, and, therefore, the absence of riparian damage, must come from the intelligent analysis of the hydrological and hydraulic data accumulated over a period of 65 years. Few hydraulic engineers have been blessed with such abundant and precise data for the determinate solution of

their problems as are contained in the records of the levels of the Great Lakes from 1860 to 1924, and in the extensive river measurements leading to the precise establishment of the laws of discharge of the several outflowing rivers concerned. Perhaps the vastness of the reservoirs and the superficial complexity of the problems have blinded even the eyes of engineers to the simplicity, certainty, and desirability of the changes suggested in this paper.

New Boundary Waters Treaty

The present Boundary Waters Treaty of 1910 between Great Britain and the United States needs to be fundamentally rewritten; and when a new treaty is made, the counsel of hydraulic engineers will be needed. It should provide for the construction of the various works suggested in this paper, and it should insure the most effective use of all regulating works, including those in the St. Marys River, for the dual purpose of navigation and water power. Diversions should contemplate such elasticity as will permit the best economic use of the water, with intermittent flow for peak-load conditions and augmented flow, if desirable, for power purposes during the winter season.

Such new treaty should, in general, determine and adjust all the various and interrelated matters which have to do with the entire question of the passing of ships from the western end of Lake Superior along all possible routes eastward to the Atlantic Ocean. The policy to be determined is one in which two nations are vitally interested and a new treaty must be broad and just. No real progress can be made and no substantial advantage can be secured except through negotiations, based squarely on equality of opportunity. Considerations of statistics, of expediency, of benefits, or of strategy of position must not be permitted to delay the solution of this great problem which looks to the economic welfare of the people of two countries.

Conclusion

This paper is of necessity long. It attempts to deal comprehensively with great projects for navigation and water power. It is intended to be constructive, provoking discussion to the end that a clearer comprehension of the engineering problems of the Great Lakes System may exist in the minds of engineers and of laymen, and that the best solutions may be devised. It is not intended to prescribe finalities, but rather to suggest the vital principles which should obtain in the engineering ways of securing ultimate benefits in this tremendous international resource of the St. Lawrence Waterway to the Sea.

DISCUSSION

H. DE B. PARSONS,* M. AM. SOC. C. E.—The biggest engineering project now (1924), under discussion concerns the development of the St. Lawrence River. The project contemplates the canalization of the river so that ocean-going vessels may enter the Great Lakes, and the development of hydraulic power between Montreal and Lake Ontario.

Much has been written and spoken about the St. Lawrence project, but a large proportion of it has been propaganda designed to awaken popular fancy. The canalization of the St. Lawrence and of the rivers joining the Great Lakes, coupled with hydraulic power development, is such a gigantic undertaking that the problem requires intensive study based on facts before any sound opinion can be reached. The engineering difficulty of damming an immense river, situated in a cold climate and lacking a low-water period to facilitate coffer-dam construction, is not the only problem. A greater difficulty is that of correctly conceiving future conditions of finance and trade, in order that the completed project may be of greatest National benefit without excessive cost.

The northern part of the Middle West is a "big" country, it has had a "big" growth—even phenomenal—and it is easy to comprehend why its people should be interested in a "big" undertaking. Projects of great magnitude always have to go through a long period of discussion and duplication of investigation. Probably it is right that they should be subjected to such scrutiny, as to remedy an oversight, error of judgment, or mistake in application would be most costly once the works were started. Mistakes and errors usually are attributable to a lack of clear understanding and appreciation of underlying principles. It is easy to sink capital in an enterprise which will not pay a return on the investment, whereas it is difficult to forecast future requirements in an age of progress, such as the present.

This paper covers the chain of the Great Lakes as well as the St. Lawrence River. The speaker concurs with the author regarding benefits that would accrue from a proper regulation of the lake levels. He is not able to follow the author's assumption that ocean-lake transportation cost will approximate the present cost of lake freight charges, as this conclusion has not been fully accepted by disinterested parties. He is not in accord with the author on costs of construction, as mentioned in the paper, because he believes they will be greater than stated, and also because the costs of deepening lake harbors and of building harbor protection works and dock facilities have not been given sufficient consideration. Nor can he subscribe to the conclusion that hydraulic power development along the waterway will subsidize canalization, because it is by no means certain that the Governments of Canada and of the United States, after constructing such power developments, can operate or lease them for the purpose of subsidizing navigation. In brief, he believes that the paper is an excellent introduction to his argument, namely, that

* Cons. Engr.; Prof. Emeritus, Rensselaer Polytechnic Inst., New York, N. Y.

the whole subject should be fully considered by an International Commission composed of disinterested and unbiased engineers.

The speaker always has believed that any project which benefits a large section of a country and a large proportion of its inhabitants is of advantage to all, even to those who cannot make use of the project nor receive any direct service from it. Prosperity or depression in one section is reflected in other sections, although it may not be evident at the time. While people in the great divisions of the United States have different aims, different interests, and different viewpoints, they are linked together by economic consideration in such a manner that their common welfare is of greater import than sectional benefit.

The entire project is in reality two projects linked together, namely, first, a ship canal through the St. Lawrence to Lake Ontario, utilizing such power as can be generated at the dams, remodeling the Welland Canal, and deepening interlake rivers and lake harbors by dredging and by lake-level regulation works; and, second, an hydro-electric power development between Montreal and Lake Ontario, using the ponds above the dams for navigation purposes, while the remodeling of the Welland Canal and the deepening of the interlake rivers and lake harbors would follow the use made by ship navigation.

Briefly, the questions are: Should navigation or power generation be the primary factor in the development of the river between Montreal and the outlet of Lake Ontario, and, which primary consideration would be the better for the States and the Dominion? These two primary factors, although closely related, should be kept separate. Dams best suited for canalization necessarily would not be the same in height or location, as those at which power generation was the dominating consideration.

The St. Lawrence is the natural drainage outlet of the Great Lakes. These lakes form immense storage reservoirs, so that the yearly flow of the river is remarkably even. The annual variation of the surface of Lake Ontario is only a few inches, with a maximum at long intervals of about 5½ ft. The uniform flow of the river is a condition favorable for power development, as it will permit the use of units of large capacity with a steady output. In this respect the St. Lawrence is unique, its normal flow being greater than that of any other river on which hydraulic power can be developed advantageously.

The normal flow of the St. Lawrence bears a relationship to the maximum flood and to the minimum discharges of other large rivers approximately as shown in Table 5.

This comparison is more favorable to the St. Lawrence than is apparent from the data given, because the maximum flood discharges last only a few hours whereas the flows approach the minimum for an appreciable part of each year.

This remarkably uniform natural flow can be improved by regulation works near Lake Ontario. It has been estimated that the flow can be controlled between 210 000 and 280 000 sec-ft. Such regulation would be of great benefit to both navigation and power development.

TABLE 5.—Relation of Normal Flow of the St. Lawrence River to the Maximum Flood and the Minimum Discharges of Other Large Rivers.

	Maximum flood discharge.	Minimum discharge.
Susquehanna, at McCall Ferry, Pa.	One-fourth	100 times greater
Mississippi, at St. Paul, Minn.	One-third	10 " "
Nile, at Assuan Dam, Egypt	Equal	10 " "
Connecticut, at Hartford, Conn.	Equal	160 " "
Delaware, at Lambertsville, N. J.	One and one-half	190 " "
Hudson, at Mechanicville, N. Y.	Twice	200 " "

The best available figures on flow of the St. Lawrence River, as measured near Ogdensburg, N. Y., are:

Maximum discharge	320 000	sec-ft., or	152%
Mean "	210 000	" " "	100%
Minimum "	191 000	" " "	91%
When ice-blocked	185 000	" " "	88%
High water in Lake Ontario (1870), in feet			248.95
Mean level of Lake Ontario (1860-1923), in feet			246.15
Extreme low water in Lake Ontario (1895), in feet			243.41
Discharge at mean level, in second-feet			240 000
Increase per foot rise of lake, in second-feet			21 500
Entire area of drainage basin, in square miles			298 080
Of which the water surface is, in square miles			95 160

The area of the drainage basin is divided between the United States and Canada, as follows:

In the United States:

Water	60 950 sq. miles
Entire	176 050 sq. miles

In Canada:

Water	34 210 sq. miles
Entire	122 030 sq. miles

The only tributary of any size is the Ottawa River, part of which enters Lake St. Louis, just above Montreal. Although this river has a wide range of flow, its effect on the general project is of minor importance, and would only affect hydraulic works near Montreal.

Some international discussion has taken place in regard to the 10 000 sec-ft. required by the City of Chicago, Ill., for its Drainage Canal. However, Lake Michigan is entirely within the United States and its basin has an area of 69 040 sq. miles. If it is assumed that the mean run-off is the same per square mile as for the entire basin of the St. Lawrence, namely, 0.8 sec-ft., then the Lake Michigan Basin contributes to the general flow 55 232 sec-ft., or 5½ times the quantity that Chicago is asking permission to take. The lowering by this taking of the general water surfaces of the lakes below Michigan, however, is a condition that affects Canada as well as other places in the

United States besides Chicago. The surface levels of the lakes (except Superior) appear to be lowering. This may be due to deforestation and to deepening of the channels connecting the lakes. This subject should be officially studied. If lake-level regulation works are required, they should be built at once, as the gradual shallowing of channels and harbors is a serious menace to navigation.

The Canadian Provinces of Quebec and Ontario have an area of about 563 700 sq. miles and a population of about 5 500 000. The States bordering on the Great Lakes (excluding New York and Pennsylvania, because they would benefit but little by the canalization) are Minnesota, Wisconsin, Michigan, Illinois, Indiana, and Ohio. These six States have an aggregate area of about 332 400 sq. miles, or about 11% of the total area of the United States, and a population of about 22 500 000 or about 22% of the total population. If the grain-growing States of Kansas, Missouri, Nebraska, Iowa, South Dakota, and North Dakota, are included as being benefited by the canalization, then the area mentioned would be increased to 765 860 sq. miles and the population to 32 900 000, which would be 25% and 31% of the corresponding figures for the entire United States.

As years pass, this nation's demand for foodstuffs will become greater, and less surplus will be available for export. Possibly, the Dominion will have surplus grain for export when that of the United States is required for home consumption.

Even under most favorable conditions only a part of the grain and other export business would seek an outlet *via* the St. Lawrence, and the question is "What part?". The business is largely bulk freight. Return cargoes would be largely package freight, requiring different conditions for handling.

Going from lake ports *via* the St. Lawrence rather than *via* New York the saving in distance to Liverpool is about 450 miles and to Southampton about 225 miles. There is no saving in distance to many foreign ports. Physical disadvantages—ice and fogs, dangers due to narrow channels and locks, and increased insurance—would offset the gain in distance. There would be, however, a saving in transshipment, and possibly a cleaning of ship bottoms, as barnacles and other sea-water growths would have a tendency to drop off in the fresh water of the lakes. The question then arises, "Would the traffic make it worth while for ocean-going vessels to navigate the St. Lawrence?". The distance from the Atlantic Ocean to Montreal, *via* Cabot Strait, is approximately 797 miles; and from Montreal to Lake Ontario, 182 miles. The approximate distance from Chicago to the ocean is 2 040 miles, *via* Cabot Strait on the south of Newfoundland, and from Duluth, 2 139 miles. These distances would be increased about 200 miles *via* Belle Isle Strait on the north of Newfoundland.

The speed of vessels using the canalized river probably would not exceed 6 miles per hour, while delays at the locks, and loss of time through fog would diminish the average speed below this limit for transit from the ocean to Lake Ontario. Assuming that loss of time by reduced speed and delays at locks would be compensated by increased speed while traversing the open water of

the Great Lakes, a vessel would require about 11 to 12 days for passage from the Atlantic to Chicago or Duluth.

The St. Lawrence River is closed to navigation by ice about four months each year. Practically the foreign shipping season would be about seven months, as ocean ships would leave port before there was danger of closing and would not enter until after the river had been opened.

The lake trade has developed a wonderfully efficient type of vessel. These vessels can carry about three times the tonnage on the same draft as a sea-going vessel, and their large hatchways permit rapid loading and discharging of bulk cargo like grain, ores, or coal. It is not uncommon for a lake freighter to discharge 10 000 tons of iron ore in 3 hours with four 15-ton electric buckets, each operating about once a minute. Lake vessels can load in even shorter time. This speed makes a quick "turn around", which is an economical feature for marine transportation. Ocean navigation is more expensive than lake navigation—a larger crew is required (about 60% larger), inspection regulations are more stringent, surface condensers are required in place of jet condensers, large hatchways are unsuitable for ocean service, and sea-going vessels cost per ton capacity from two to three times that for lake steamers. To-day's lake freight charges per ton-mile, therefore, are not applicable to vessels that are suitable for a trans-oceanic service. It might be possible to develop a new type of vessel—a combination, so to speak, between sea-going and lake types—but could such specially designed vessels afford to be laid up for more than one-third of each year while the waterway was ice-bound?

The St. Lawrence below Montreal has a minimum depth of about 30 ft. Between Montreal and the outlet of Lake Ontario, the river is navigable in part, and Canada has a series of canals about 14 ft. deep around natural obstructions. The Welland Canal has a depth of about 25 ft., with 30 ft. on the lock sills. The Detroit River has been excavated in rock to a normal depth of about 23 ft. The lake harbors have different depths, in general, from 16 to about 22 ft.

Before undertaking the canalization of the St. Lawrence, primarily for the purpose of navigation, it will be well to make sure that ocean-going ships will patronize it. As the power possibility is great, it would seem a pity to minimize it for a canalization project that was not founded on sound judgment. There is little doubt that the full power of the river is needed, or soon will be needed, especially in the United States. The question to be settled is: "Should not the river be developed to best advantage for power generation, and then make use of the pondages for navigation?".

The St. Lawrence water powers are not equalled by any river in North America. Its nearness to a power market is undisputed. There is little danger that private interests alone will benefit. The Government will safeguard its rights, and public service commissions will have a voice in regulating prices and in determining the manner in which current is sold. There can be no question that the cost of development by private enterprise will be less than by the Government. As interest on the cost forms one of the largest items of annual charges, it is clear that the lower cost will make cheaper rates for power.

Rated power of prime movers in the United States is growing more rapidly than the population; in other words, there is more horse-power per capita now than formerly, and there will be still more in the near future. The Federal Power Commission has compiled data as shown in Table 6.*

TABLE 6.—Data Relative to Population and Power Consumption in the United States, 1905 to 1930.

Year.	1905.	1910.	1920.	1925.	1930.
Population	85 000 000	92 000 000	109 000 000	113 000 000	119 000 000
Power consumption, total rated horse-power	20 000 000	26 000 000	42 000 000	50 000 000	59 000 000
Rated horse-power per capita	0.235	0.282	0.385	0.442	0.495
Increase in percentage	.....	20	64	89	110

The figures given in Table 6 are significant. The rated power of prime movers per capita has increased in 20 years (1905-25) about 89%, and will increase in 25 years (1905-30) about 110 per cent.

The figures in detail indicate a decreasing tendency in horse-power per capita generated by manufacturers, and a rapid increase in rated capacity for electric railways and central stations. The figures show the importance of large central stations for the generation of power, with their inherent economies, and the demand that will be made on the St. Lawrence for the utilization of its power.

The chief link of the project is the 182 miles between Montreal and Lake Ontario. As the lake is about 247 ft. above mean sea level, and as the river at Montreal varies in depth from about 16 to 23 ft., the gross available fall is about 224 ft. Of this reach of the river, 113 miles, with a fall of 93 ft., forms the International Boundary, while 69 miles, with a fall of 131 ft., is entirely within the Canadian border. In brief, 62% of the distance and 41½% of the power is divided equally between the United States and the Dominion; and 38% of the distance and 58½% of the power is owned entirely by the Dominion. Therefore, the United States, or more correctly speaking the State of New York, owns 20¾% of power, while the Dominion owns 79¼ per cent. The State has riparian rights covering 62% of the total distance; while the Dominion has rights covering 100 per cent.

On the basis of a mean flow of 210 000 sec-ft., a total fall of 224 ft. between Lake Ontario and Montreal, and an efficiency of 70% (to allow for mechanical losses and losses of head that cannot be recovered), there would be 3 741 000 potential h.p. This estimate is subject to refinement by load factor, diversity factor, transmission-line losses, conditions governing a super-power system, and loss of water due to lockages by passing ships. Regulation works would increase the available horse-power, as the lakes would be storage reservoirs.

Of the total stated, the Dominion, with a fall of 131 ft., has about 2 188 000 potential h.p. The power that lies on the International Boundary has a fall

* "Super-Power and Its Public Relations," by Herbert Hoover, Hon. M. Am. Soc. C. E., *Military Engineer*, July–August, 1924.

of 93 ft., which would give 1 553 000 potential h.p., of which the State of New York (or the United States) would own one-half.

There would have to be an agreement between the United States, the State of New York, and the Dominion of Canada, before any construction work were undertaken, either for canalization or power development. If the two National Governments equally divided the cost of construction and cost for flooded lands, the United States would have to pay for deepening its own lake ports and harbor protection works, as well as its share of blasting and dredging the interlake rivers and canals. If the canalization were made for 30-ft. draft and the full hydraulic power developed, the total cost to both Governments might exceed $1 000 000 000, without any allowance for transmission lines.

There are many vital questions to be settled, such as, what shall be the minimum depth of canal? Shall it be for vessels of 21-ft., 25-ft., or 30-ft. loaded draft? Where should the dams be located? What is the geologic structure at the proposed sites? What is to be size for locks? Should lake-level regulation works be constructed? What should be the rated capacity for generators? What load factor can be expected? What would be the cost?

The speaker believes that both Governments should unite in the appointment of an International Commission, composed of the highest grade of engineers, which should outline its recommendations in interim reports. These interim reports should be published so that constructive criticism might be received. When its final report is accepted, and an agreement between the Governments is reached, the works could be started. If a "plan and policy" for a comprehensive development of the St. Lawrence were adopted, there would be no good reason why part could not be done by the Governments and part by private interests, should such a division be deemed the most economical and the quickest procedure.

Let the investigation be full, because ordinary propaganda will not finance a great undertaking. Facts alone must guide those seeking the solution of a complicated problem.

H. C. Sadler,* Esq.—In all large undertakings, especially those of a public character, numerous and conflicting interests are bound to be involved. When, in addition, projects that affect international as well as sectional interests are introduced, the field for discussion and criticism is expanded still further. Therefore, in the case of the Great Lakes-St. Lawrence Waterway, it is only natural to expect not only criticism, but opposition, and from its very nature, opposition of a somewhat violent character.

Although it will be generally conceded that certain points are debatable, on account of the mass of facts which can be summoned to support each side of the controversy, it is necessary that, in order to receive any consideration in the argument, the facts as stated should be true. Otherwise, the whole

* Prof. of Marine Eng. and Naval Architecture, Univ. of Michigan, Ann Arbor, Mich.

fabric, although for a time appearing to be substantial, must eventually collapse, as its foundation rests on a quicksand of imaginations or mistakes.

A sage of old time once said, "Would that mine enemy would write a book", and in connection with the project under discussion, many books, pamphlets, reports, etc., have appeared which contain arguments against the proposition. In this mass of literature one finds numerous statements which, to say the least, are misleading and others that are absolutely untrue.

In this discussion the speaker proposes to deal simply with matters affecting ships and their operation, and leave the other points of controversy, which involve power developments, international and sectional questions, to those whose training and experience qualify them to pass an opinion; if this method had been followed in the past, the amount of chaff in the wheat of the literature would have been reduced considerably.

Although some of the speaker's statements may have appeared before, they will bear repetition, first, because they have been somewhat lost in the mass of the literature; and, second, because such repetition may help to brand as utterly false certain other statements that may have passed muster as the truth.

Perhaps one of the most important points at which those who are interested in the questions relating to the engineering features and those of transportation meet, is in regard to the question of depth of water in the channels and canals. This ultimately affects the draft available for ships. Rather than go into a mass of figures and technicalities as to sizes of vessels, the speaker will present the actual facts of overseas transportation, to show what the world has done and is still doing.

Every maritime country in the world has several ports that may be classified as "major" and "minor". An examination of "Lloyd's Register of British and Foreign Shipping" will show the depth of water available in every part of the world. With comparatively few exceptions this depth varies from about 30 ft. to 24 ft. for the major ports and from 24 ft. to 14 ft. for the others. All these ports are doing business, so it is somewhat hard to reconcile with the actual facts such statements as the following: "24 ft. is the minimum draft that can be operated profitably", or "there are no vessels * * * profitably operated in ocean service drawing as little as 18 ft.", or "all sizable ships engaged in foreign commerce draw in excess of 30 ft.", or, again, "the average draft of ocean-going vessels is from 30 to 35 ft."

The great mass of the world's commerce is not carried by the *Leviathans, Majestics,* etc., but by the cargo or tramp steamer, and as a matter of fact more than 70% is carried in vessels of less than 5 000 tons or, say, 7 500 tons dead weight, and on a draft of less than 25 ft. If a channel 30 ft. deep is provided, it would be available to nearly 90% of the vessels of the world. The figures can be verified by reference to "Lloyd's Register".

There has been a great deal of comment on and objection to the fact that even with a 25-ft. channel, the speed of a vessel would be considerably reduced. Others have made it appear that at least 5 to 6 ft. of water would be required below the keel of a vessel to maintain a speed of 12 miles per hour, and from

this they argue that a draft of only 19 to 20 ft. could be used on a 25-ft. channel. Although it is true that, in restricted channels and shallow water, the speed would be reduced, even to, say, 5 miles per hour, the percentage of time so lost as compared with the whole voyage is insignificant. What again is the experience of vessels operating in the open seas? It is common knowledge that through stress of weather, fogs, etc., vessels are often delayed one or two days or even longer on a given voyage, and yet vessel owners do not give up their business because of this fact. It is absurd therefore to state that a vessel requires 5 or 6 ft. below her keel to maintain full speed through channels, even if this were possible from other consideration as to the canal banks, etc.; and, moreover, actual experience with ships shows that owners will load their vessels to the maximum safe limit of draft, and take the small delay due to reduced speed. The profit due to the extra cargo thus carried would seem to be evident, even to a layman of ordinary intelligence. On the Great Lakes the vessels operate through the shallower channels, not with some feet of clearance, but more often with inches, and do so successfully.

It is absolute nonsense therefore to make a mountain out of the molehill of reduced speed over an insignificant part of a voyage, particularly when one considers that the average speed of a freight train is about 4 miles per hour, or less, when terminal and other delays are taken into account; and yet the speaker ventures to suggest that, in proposing a new railroad, these delays would not deter its construction.

Another objection has been raised to the proposed waterway, in that it would be open for only about 7½ months in the year, and, therefore, that the business would be seasonal. With the exception of the trade by regular liners to the larger ports of the world, all the general ocean trade is seasonal. A prominent ship-owner once told the speaker that operating a freight vessel itself did not require much effort, but the really successful ship-owner was the man who knew the geography of the world and where cargoes were to be had at different times of the year. One need only call attention also to the Baltic trade where somewhat similar conditions pertain.

Cargo vessels to-day are navigating the whole globe, and often go long distances, even in ballast, to pick up a cargo. To argue that a vessel would not come up into the Great Lakes because it is so far, is laughable, and to state that: "Vessels will not find it profitable to gather up partial cargoes", and "such attempted service would be entirely unprofitable and uneconomic", shows a pathetic ignorance of facts. When one considers the long ocean voyages that vessels make, without any port of call, it is inevitable that the great area of the Middle West economically adjacent to the Great Lakes, with its numerous ports, and with a tremendous producing and absorbing power, would prove an attractive and profitable field for the cheap form of transportation offered by ships. Again, the speaker would call attention to the successful operation of vessels from the eastern coast of the United States to the Pacific ports, in competition with the much shorter rail haul, to emphasize the fact that actual distance does not act as a deterrent.

Finally, also, even with the restrictions of the present Welland Canal, with its limits of about 250 ft. in length and 14 ft. in draft, Norwegian, Swedish,

Danish, Canadian, and other vessels have been operated in the past and are to-day operating through the Great Lakes. This last consideration brings up another argument, of a somewhat specious character, that has been used against the proposed waterway, namely, that ocean-going vessels could not compete with those of the Great Lakes, or that the latter could not operate on the open seas.

All the world over there are special types of vessels designed to do specific work. If changes were made in design so that they would be a compromise between two different sets of conditions, they would probably be failures in both. The lake freighters are the last word in a type of vessel especially developed to do the business of carrying bulk commodities, such as iron ore, coal, etc., in the most economical way, between the different lake ports. Their business is on the lakes, not on the ocean, and experience shows that, even with the bogie of a restricted season, they can be run profitably. To alter the design to allow them to go to sea would be suicidal, and almost as absurd as to suggest putting a passenger vessel of the Hudson River Day Line into the North Atlantic trade, when the summer excursion season was over. No, the function of the ocean-going vessel would be to carry commodities to and from the Great Lakes and the remainder of the ports of the world, including even those on the east and west coasts of the United States. She would not, and, if a foreign vessel, she could not, according to the coastwise shipping law, engage in inter-lake commerce; but lest the opponents' arguments should be taken too seriously, the speaker will quote two which are destined to appeal to the sense of humor of any one connected with ships. The first is as follows:

"Lake vessels with their flat bottoms have a capacity of 14 000 tons, but ocean-going vessels with different keels would be limited to a capacity of not more than 4 000 tons, * * * ."

The shape of the mid-ship section and the bottom is identical in both lake and ocean cargo vessels, and although some of the former may be of a little fuller form at the ends, there is absolutely no difference for the middle body. Again, in criticizing a statement in McElwee and Ritter as to the cost of a large lake vessel, an enthusiast makes bold to say* that "the present cost of such a vessel is about $400 000, or a little over one-third of the amount stated [$1 100 000]". At one time, before the World War, a vessel of 10 000 tons was built for about the sum quoted, but not since then, as any one can find out by inquiring of any lake ship-builder. Consequently, the critic's statement that the figures quoted in the book are "utterly unworthy of trust", should be politely returned to him with the suggestion that it is always the part of wisdom to make sure of one's own facts before contradicting others that are true.

A final argument which is somewhat related to the foregoing, is that ships of a peculiar type would have to be specially designed for this service. This is nonsense because any vessel within the limit of draft available could use the Welland Canal and the great open waterways of the Great Lakes, in precisely the same way as it does at present all over the world. One does not

* Twelfth Annual Rept., New York State Waterways Assoc., 1921, p. 44.

hear of specially designed vessels to navigate the Delaware River, or the River Clyde, or the Suez or Manchester Ship Canal waterways where ships take the time and risk of restricted navigation in order to reach the final port. It is nevertheless true that vessels for some particular class of work might require special designs, in order to obtain the maximum efficiency for that special service. If so, the problem presents no difficulty to the naval architect or ship-builder, and is nothing more than he is continually being called on to solve. Most of the coasting types and lake package freighters could be used for coastwise service on this route without any modification. Perhaps one might interject the thought here that, after all, large numbers of the trans-Atlantic liners are very specialized types for that particular trade and, as such, do not represent the trading vessels of the world.

The following general conclusions may be drawn, not necessarily from masses of minute computations, or timid predictions as to the future, but from a common-sense consideration of what vessels are actually doing to-day all over the world, and from past experience of developments due to increased water-transportation facilities:

1.—There is nothing to hinder existing sea-going vessels up to about 7 500 tons dead weight, or even a little higher, from utilizing the proposed St. Lawrence route to reach the great productive Middle West.

2.—Delays from locks, fogs, ice, and reduced speed in shallow waters, representing only a small percentage of the time of a voyage of an overseas vessel, are difficulties that have fallen to the lot of the ship-owner from time immemorial and form no serious obstacle. Fog particularly is rapidly losing its menace with recent developments in submarine signaling.

3.—Vessels will always go where trade is to be had, irrespective of the fact that it may take a little longer to reach a certain destination; and the Middle West, with its numerous lake ports, has already shown its productive and absorptive power, as reference to trade statistics will show.

4.—If special types of vessels for the intercoastal trade should be desired for any specific purpose, their design would present no difficulties. In this connection, it may be remarked that the actual coast line of the United States and Canada available for coastwise shipping will be increased thousands of miles by opening up the Great Lakes to the Atlantic Ocean. This alone has enormous possibilities for increased trade.

5.—It is absurd to talk about competition between special lake types and ocean-going or overseas vessels, as each performs an entirely different kind of service.

In conclusion, and referring again to past experience, it is the man with the broad vision, undimmed by the immediate existing order of things but looking to the future, who has been responsible for the progress of the world.

The United States and Canada are new countries still possessing tremendous possibilities for future development both in material and population. Cheap transportation is the essence of trade, and the speaker ventures to suggest that, in the years to come, the proposed Great Lakes-St. Lawrence Waterway, the New York State Barge and Erie Canals, and the Mississippi River,

will not only prove inadequate for the tasks imposed on them, but that even other waterways already suggested will be necessary for the economic life of the two countries; and, then as now, the two great banking centers of Montreal and New York will still continue to feel an enhanced benefit from a prosperous and busy Middle West, even if they may lose a few dollars in tolls on shipping.

F. P. WILLIAMS,* M. AM. SOC. C. E.—In this paper there is presented an extended description of the St. Lawrence navigation project, the cost of which it is proposed to pay from power developed along the Niagara and St. Lawrence Rivers.

Much convenient data regarding present conditions are furnished. The description of present conditions along the route from Duluth to the sea is of special interest. Many phases of the subject are discussed, with references extending back twenty-five or thirty years, showing the author's familiarity with the subject.

Although the author (page 469), refers to the control works on the Niagara River for the dual purpose of maintaining the best available depths, and, at the same time, of creating storage for water power in the Niagara and St. Lawrence Rivers, he does not make it clear in this or in the varied references to navigation and water power intermixed throughout the paper, that the principle of regulation shall conform to the requirements of navigation at all times, and that the development of water power shall be subordinate to navigation requirements. The accepted principle is that water power shall be subordinate to navigation.

In the following discussion the speaker desires to consider various points under their respective headings.

The Subsidizing of Navigation by Water Power.—In the paper it is stated, in numerous places, that water power should subsidize navigation. For instance (page 475):

"* * * that the construction of this waterway is inevitable, * * *, and that a demonstration of its commercial feasibility is unnecessary."

Again (page 475):

"It is of little concern whether the Rapid Sections of the St. Lawrence Waterway to the Sea has in the first decade a commerce of 5 000 000 or 20 000 000 tons."

Again (page 479):

"* * *. The undertaking is, therefore, a commercial project and the United States does not need to contribute toward its cost."

The advantages accruing to navigation by using power to subsidize it are gained at a corresponding sacrifice of the rightful advantages belonging to power. Both navigation and power are important necessities. There has been a great deal of looking forward to advantages to be obtained from large quantities of power commercially developed on the St. Lawrence River.

* Secy. Engr., New York Water Power Comm., Albany, N. Y.

No general advantage is obtained by helping navigation at the expense of power.

With a liberal supply of power ranking high as an essential of economic welfare and modern comfort, and with navigation a prime necessity, it is well to consider the benefits derived from each, and also to consider financing that will not sacrifice the benefits to be derived from power to the cause of navigation, important as navigation is. The subsidizing of navigation by water power, as advocated by the author, is opposed to this and is open to serious criticism on that account.

Comparison of Waterway Improvement with Cost of Power Development.—It is important to note the trend in plans for the improvement as shown by a comparison of the Government Deep Waterway plan for navigation, made in 1900 and revised in 1918, with the Wooten-Bowden plans submitted to the International Joint Commission in 1922. In the first plans, navigation alone was considered. The scheme was to improve the International Section of the river by a series of dams and locks, and to construct a channel so as to reduce the velocities to conform with the requirements of navigation. It was not planned to extend the dams across the river, forming power dams, and thus change conditions by flooding. The total cost of such plans, revised to 25-ft. draft, in 1918, was estimated at $33 962 772. This estimate is doubtless low on the basis of current prices.

The plans of the engineers reporting to the International Joint Commission in 1922 assume the construction of extensive dams that will raise and change the river elevation extensively, and create power possibilities of almost 2 000 000 h.p. Such plans are natural in view of the trend in the power industry. The tremendous growth in the demand for electric power and the improvements in transmission make it feasible to develop the St. Lawrence power at this time, whereas, at the time of the early studies, such development was out of the question. The cost of the International Section, according to the engineers' estimate, is $201 850 583, of which $135 047 264 is chargeable to power. Thus, it is seen that a navigation project, with navigation alone in view, may be had for about one-fifth of the present-day estimate for the combined project. Incidentally, in the latter project, two-thirds of the cost is chargeable to power.

No one desires for this river waterway improvements that cannot be adapted to the full utilization of power. Similarly, no one desires water-power improvements that do not fully conform to navigation requirements. The point worth considering is the relative amounts of money required to secure power and to secure navigation. This unique proposition as offered urges undertaking a navigation project and combining with it a power project costing from four to five times the amount of the navigation project alone and, incidentally, making power pay for the entire improvement.

New York State's Interest in Waterway.—In recent years, New York State has paid more than $160 000 000, without outside aid, to connect the St. Lawrence River and the Atlantic Ocean, for the purpose of lowering rates and for carrying American shipments through American ports. The State owns

one-half the bed of the St. Lawrence River along its border, and is the natural agency to develop and control the power on the St. Lawrence.

New York State will be required to pay a large percentage of the cost of the proposed project, in the ordinary procedure of paying her share of Government expenditures. The plan proposed by the author amounts to making New York State alone pay the entire cost of the navigation project in so far as the Federal Government's share of the enterprise is concerned. This to be brought about through increased charges for power due to the increased cost placed on power developments to cover navigation improvements. It is one thing to contemplate a great enterprise such as this, when the advantages of the main objective—the waterway—stand out as warranting the investment; it is another thing to contemplate this enterprise in so far as New York State's interests are concerned, as appraising the Barge Canal as an "escape" from the Niagara to the Hudson River, and as giving New York interests in the water power along the Niagara and St. Lawrence Rivers over to the benefiting of navigation interests, without regard to whether or not the improvements in the waterway are warranted.

Chicago Diversion.—Under the heading, "Water Power" (page 482), the author assumes that the diversion of 10 000 cu. ft. per sec. at Chicago will continue for a number of years. No reference is made to the fact that a case is pending in the United States Supreme Court between the Government and the Sanitary District of Chicago to enjoin the Sanitary District from diverting more than 4 167 cu. ft. per sec. from Lake Michigan.

Subsequent to the presentation of Mr. Shenehon's paper in October, 1924, the Supreme Court granted to the United States an injunction restraining the Sanitary District of Chicago from withdrawing more than 4 167 cu. ft. per sec. from Lake Michigan after March 5, 1925. A revocable permit was issued by the Secretary of War dated March 3, 1925, based on the recommendations of the Chief of Engineers. The significant part of the permit relating to the author's assumption of a continued diversion of 10 000 cu. ft. per sec. from Lake Michigan at Chicago, is as follows:

"* * * to divert from Lake Michigan * * * an amount not to exceed an annual average of 8 500 cubic feet per second * * *."

* * * *

"That the Sanitary District of Chicago shall carry out a program of sewage treatment by artificial processes which will provide the equivalent of the complete (100%) treatment of the sewage of a human population of at least 1 200 000 before the expiration of the permit.

"That the Sanitary District shall submit for the approval of the Chief of Engineers and the Secretary of War plans for controlling works to prevent the discharge of the Chicago River into Lake Michigan in times of heavy storms. These works shall be constructed, in accordance with the approved plans, and shall be completed and ready for operation by July 1, 1929.

"That if, within six months after the issuance of this permit, the City of Chicago does not adopt a program for metering at least 90% of its water service and provide for the execution of said program at the average rate of 10% per annum, thereafter, this permit may be revoked without notice.

"That if, in the judgment of the Chief of Engineers and the Secretary of War, sufficient progress has not been made by the end of each calendar year in the program of sewage treatment prescribed herein so as to insure full compliance with the provisions of Condition 4, this permit may be revoked without notice.

"That this permit, if not previously revoked or specifically extended, shall cease and be null and void on December 31, 1929."

The significant part of the recommendations of the Chief of Engineers relative to the assumption by the author of the continued diversion of 10 000 cu. ft. per sec. from Lake Michigan at Chicago, is as follows:

"7. * * *. (The execution of sewage treatment program which will relieve the load on the Drainage Canal by the equivalent of a population of 1 200 000 * * * will make possible a reduction in the amount of diversion to 7 250 cu. ft. per sec., or lower, by the end of 1929). This condition looks to a reduction to 4 167 cu. ft. per sec. by 1925."

* * * *

"12. * * * Condition (3) (The construction of controlling works to prevent the Chicago River from discharging into Lake Michigan in times of heavy storms * * * should be ready for operation July 1, 1929), is considered necessary to permit an ultimate reduction of the diversion to 4 167 cu. ft. per sec."

Engineers are left to their own conclusions regarding the appropriateness of such an assumption by the author, that the diversion of 10 000 cu. ft. per sec. at Chicago will continue for a number of years.

Conservation of Coal Supplies.—Under the heading, "Value of Added Water" (page 493), the author states that there is no vital concern in regard to the saving of bituminous coal, because at the present rate of consumption the visible supply in the United States will last for more than 5 000 years.

The following is quoted from a *Bulletin* dated August 1, 1922, issued by G. H. Ashley, State Geologist of Pennsylvania:

"Bituminous Coal Reserves in Pennsylvania, in Short Tons, 1922.

"Original deposit	75 259 055 000
Mined out	5 519 665 000
Recoverable	43 830 860 000"

If the mining of bituminous coal at the rate of 170 000 000 tons per year is continued, the bituminous coal in Pennsylvania should last about 250 years. For years the State of Pennsylvania has supplied about one-half the coal used in the United States. It is true that the coal originally estimated to be underground in Pennsylvania constitutes only a very small percentage of that in the whole United States, but the point is that (1) the State of Pennsylvania is depended on to-day to furnish a large quantity of coal because it exists there in thick veins; and that (2) the cost of coal is mounting. There is only one conclusion, that while estimates may show a supply of coal sufficient to last a long term of years, there should be vital concern about how long the supply of cheap coal will continue. All water power should be developed as early as it is economical to do so, for the purpose of conserving the coal supplies.

Radius of Economic Benefits from Water Power and from Navigation.—Under the heading, "Water Power and Navigation" (see page 481), the

author states that while the economic benefits of water power may be limited to 200 miles, navigation may benefit an area in a radius of 2 000 miles. It is difficult to assign specific distances, as the author has, to either range of benefits when the indirect and intricate benefits involved in manufacturing aided by navigation or by power, or by both, are considered.

The manufacture of some of the electro-chemicals, paper, etc., is only feasible when large quantities of cheap hydro-electric power are available. In such instances, instead of limiting the benefits from hydro-electric power used in such manufacture to 200 miles, it is more nearly correct to estimate that the benefits are country-wide. It is possible that the author has in mind simply the feasible distance that power may be transmitted. Plans advanced for disposing of St. Lawrence power contemplate transmitting it 300 miles to New York and elsewhere.

Summary.—Only a part of the paper is here discussed, the speaker's remarks being made to give students of the project information from which they may see what the situation is, namely, that the author is advancing a plan to nationalize the water-power interests of the State of New York along the Niagara and St. Lawrence Rivers, making the power subsidize navigation improvements, without even taking the trouble to justify such action from either the legal or economic standpoint. The speaker heartily disapproves of this plan.

The author has spoken of opposition as stimulating. It is hoped that as a result of this suggestion, a discussion of all phases of the points touched upon regarding this important subject will be had.

THOMAS H. HOGG,* M. AM. SOC. C. E.—The author is to be congratulated on the excellent manner in which he has presented his description of the projected waterway to connect the Great Lakes and the sea.

The speaker will endeavor to point out certain fallacious reasoning that has led to serious erroneous conclusions on the part of the author. He assumes that water power should be charged with the cost of navigation development on the St. Lawrence River. There are two possible conditions under which a justification of this assumption might be considered:

1.—That the development of water power causes existing navigation structures and channels to become inoperative.

2.—That the benefits derived from the power developed are shared by districts and interests identical with those benefited by the navigation works.

Present conditions on the St. Lawrence River provide for navigation with a draft of 14 ft., whereas the author's proposal is for deep-draft navigation. It would be reasonable, under certain circumstances perhaps, for power developments on the river, if they destroyed existing works, to be charged with facilities equivalent to those existing, but it is quite unreasonable to expect a power development to go beyond the existing facilities and pay the whole of the enormous increased cost occasioned by the construction of greatly improved river channels, canals, and locks suitable for vessels six or eight times as large as those now accommodated by the existing canals.

* Chf. Hydr. Engr., Hydro-Elec. Power Comm. of Ontario, Toronto, Ont., Canada.

At present, power is transmitted to points about 250 miles distant from generating stations, so that potential developments are of possible value throughout a circle described by this radius. This transmission distance may, perhaps, be somewhat extended in years to come, but at present, and to a greater or less extent in the future, it gives a measure of the district benefited by a water-power development, and also a measure of the district which must pay through power rates for the development and for all the works provided for in the construction cost of such development.

On the other hand, navigation benefits in this particular instance extend far beyond this radius of 250 miles, and, in fact, reach their utmost value in a district greatly removed from the locality of the power development. The districts that would be especially benefited by the construction of deep-draft navigation works on the St. Lawrence River are the eastern section of the Prairie Provinces in Canada and the Central United States.

The conclusion to be reached, therefore, is that, according to the author's assumption, industry and other power users in the district bounded by Toronto, North Bay, Quebec, Boston, and Rochester, should alone pay all the cost of these navigation works, which would benefit primarily the district west and southwest of Detroit.

Engineers and financiers are quite conversant with the economic aspects of the construction of water-power plants and of the somewhat temporary nature of the market and employment involved therein. The relation of the water-power development to the permanent market for raw materials, production of manufactured goods, and development of permanent employment in other industries, is not so well appreciated and, in fact, by many, is not appreciated at all.

An analysis of these general aspects of the problem under consideration, aided by a special census in the United States, shows that of the whole investment in a water power and the industries built up by it, only 13.4% is found in the water-power development, and 86.6% in the applications of the power. In the matter of employees, less than 3% of these are engaged in the production of power, and more than 97% in industries utilizing that power. The wages paid are 2.3% of the total for water power, and 97.7% in application of this power.

Very great and widespread benefits are received by all people and interests in the district affected by the production of power through the application of that power to industry; but the benefit derived from the power *per se* is usually small, accounting as it does in its tolls for less than 3% of the business of the district. Thus, power development is in the same category as navigation works, and instead of being forced to pay tribute, water power might more fairly be subsidized.

The author indicates that by regulation works constructed at the outlets to Lake Huron, Lake Erie, and Lake Ontario, in addition to those existing on the St. Marys River, a dependable flow of 230 000 cu. ft. per sec. can be obtained for the St. Lawrence River on the assumption that 10 000 cu. ft. per

sec. now diverted at Chicago passes to the sea by its former and natural course. The argument appears to be—although not so stated—that, since the power capacity on the Niagara River and on the St. Lawrence River is increased by this regulation of the Upper Lakes, the people in districts to be served by these power developments should pay the whole cost of the necessary regulating works which are so vital for navigation.

A comparison is made by the author of the results to be obtained by regulation of the St. Lawrence River, according to the Government engineers' report on the St. Lawrence Waterway, and the results, he asserts, can be obtained by complete regulation of the Upper Lakes. It must be kept in mind that, in the various studies of regulation already made, different objectives are set. In some cases this objective has been the maintenance of a large flow in the Lower St. Lawrence River during September, October, and November; in others, the maintenance of proper winter operating conditions; or, again, the maintenance of a high uniform flow. In passing, it may be noted that it is quite possible to obtain a higher minimum flow by the regulation of Lake Ontario alone than the author quotes from the Commission Engineers' report, for purposes of comparison with his figure of 230 000 cu. ft. per sec. It must always be kept in mind that, although artificial regulation, even after a subtraction for the Chicago diversion, may give better results than those obtained under natural conditions, yet the results would be just so much better were there no diversion at all at Chicago. In other words, the diversion at Chicago and the regulation of the lakes are two perfectly independent matters.

There are certain other points on which exception might also be taken, for example, the author's assumption that there would be no break in cargo at Montreal after the construction of the deep waterways. It is conceivable that economic operation will involve the use of large lake freighters from the Upper Lakes to Montreal and transshipment there to sea-going freighters.

One must, of course, at this time speak with caution respecting the diversion of water at Chicago, for although this is a most important international matter, yet at the present time its domestic aspect, as far as it concerns the United States, is under consideration by the Supreme Court. It may be that the author's conclusion that for the next fifty years, that diversion will be at least 10 000 cu. ft. per sec., may not be borne out by that decision.

Although several relatively minor causes of lowered lake levels are noted by the author, nevertheless proper emphasis has not been placed on the level-lowering effect of the Chicago Drainage Canal, which removes water not only from the navigation channels, but entirely from the water-shed, thereby lowering all lake levels except that of Lake Superior and all river levels from that lake to the sea. In this connection it is not practicable to compensate the St. Lawrence River for its loss.

The author's apparent concern in regard to the failure of power development companies to expend money for ice protection at the outlet of Lake Erie is probably due to the fact that he has failed to recognize, in the present

instance, that power development engineers are unable to spend millions of dollars for accessory works that cannot be made to return a justifiable income on the money invested.

L. C. SABIN,* M. AM. SOC. C. E.—It is refreshing to have such a comprehensive paper devoted to the Great Lakes Basin and the water power possibilities of its final outlet to the sea presented by one who has given much time and thought to the collection of data concerning it, and to the subsequent study and application of these data.

The author is correct in his assumption that the justification of a deep waterway outlet from the Great Lakes to the sea must be found, from the point of view of navigation, in the length of ship channels already available and intensively used in the Great Lakes themselves which would be tapped by such a deep-water outlet. Duluth, at the head of Lake Superior, 1 000 miles by steamer from Buffalo, is only 200 miles nearer, by airplane, to the east coast of Maine than to Seattle. As the crow flies, Chicago is equi-distant from Denver, New Orleans, and Quebec.

The advisability of building the St. Lawrence waterway at this time has been the subject of much discussion. The promoters of the project doubtless have grossly overestimated, at least by inference, the amount of traffic which it would serve in the immediate future, and the resulting saving in transportation costs. The speaker has seen no well considered study of this economic question, and from the standpoint of navigation it is a study that should precede, or at least coincide with, the study of the physical facts.

If the St. Lawrence improvement were for the sole purpose of navigation, it is doubtful whether its cost could be justified, even with the advantage of its connection with lanes of commerce already established over which traffic is hauled at a cost hardly approached by any other system of transportation except on the ocean. Fortunately, however, it is not merely, and perhaps not mainly, a navigation matter. The value of the water power is such that whenever the large blocks of power developable can be sold advantageously, the returns should pay interest on the entire cost, and, in a term of years, amortize the investment as well.

While those in favor of the project may have painted too glowing a picture of the probable volume of commerce and the consequent benefits to be derived from cheap carriage, the opponents, on the other hand, have attacked the estimated cost on the ground that the improvement of the Great Lakes channels must be a necessary part of the plan, and that the cost of such improvements should be included in the estimate.

It is well known that a large part of salt-water commerce is carried on drafts of 25 ft. or less. The tentative plan for the St. Lawrence provides for this depth at present, with a possible increase to 30 ft. later should this become desirable. The same idea is applied in the new Welland Canal. It may be assumed that a navigable depth in excess of 25 ft. in the improved St. Lawrence will not be undertaken until ocean-going tonnage has so increased as

* Vice-Pres., Lake Carriers' Assoc., Cleveland, Ohio.

to make it an economic measure. Accordingly, present consideration may be confined to the justification for a navigable depth of 25 ft. on the present commerce lanes of the Great Lakes as well as on the St. Lawrence outlet.

The importance of the commerce on the Great Lakes is not generally appreciated. In volume it equals the foreign commerce of all ports on the Atlantic, Gulf, and Pacific coasts. It exceeds the freight carried on 297 rivers, canals, and navigable waterways of the United States, including 37 well-known streams, such as the Ohio and Mississippi Rivers, and their tributaries above New Orleans, the Hudson River above New York, the Delaware River above Philadelphia, etc. These figures exclude that part of the river traffic attributable to ocean ports, such as New York, New Orleans, Philadelphia, etc. More tonnage passes the Sault canals annually than the combined traffic of the Erie, Manchester, Kiel, Suez, and Panama Canals. The average eastbound cargo at the Sault canals in 1923 was nearly 7 000 tons, while the average cargo on the Panama Canal was about 5 600 tons.

Not only in volume, but particularly in length of haul, do the Great Lakes channels exceed other waterways, exclusive of ocean tracks. The ton-mileage of the Great Lakes is about sixteen times that of the thirty-seven waterways mentioned. For the year 1923, it was equal to about one-sixth the ton-mileage of all the railroads in the United States.

The author quotes from the Presidential Address of the late Alfred Noble, Past-President, Am. Soc. C. E., of 1903, in which, on the basis of the actual freight rate on the lakes of 0.89 mill and the estimated rail rate of 3 mills per ton-mile, the saving in freight charges for the single year, 1902, was estimated at $63 000 000. The question may be raised as to how this saving is distributed, and it may even be thoughtlessly suggested that the lake transportation interests are the principal beneficiaries. A moment's consideration, however, will show that it is the same kind of a benefit as that resulting from a time-saving improvement in the making of steel and the grinding of flour, and that the beneficiaries are those who buy the ultimate products, whether wash-boilers or steel bridges, brown bread or Parker House rolls.

In the twenty-one years that have elapsed since 1902, the year of Mr. Noble's comparison, that part of the Great Lakes commerce that passed to and from Lake Superior has amounted to 1 337 000 000 tons, and the freight charges to $1 000 000 000, with an average rate of 0.9 mill per ton-mile. Using the figure of 3 mills per ton-mile as comparative rail cost, the saving in freight charges amounts to $2 300 000 000. Subtracting from this the cost of all channel and harbor improvements on the entire Great Lakes system, there remains a net saving of $2 000 000 000, the interest on which at 3% is $60 000 000 per year. With such a surplus to the credit of Great Lakes channels no hesitation need be felt in advocating further expenditures whenever the needs of the growing commerce require more adequate facilities.

The author mentions the value per inch of draft as $500 000 for one year. This figure is not a guess but an estimate based on the actual number of passages of loaded vessels of the larger classes during 1923, which showed an increase in carrying capacity of more than 3 000 000 tons for an increase in

draft of 6 in. At the average freight rate of 88 cents per ton this would amount to very nearly $3 000 000 extra earning capacity, reduced only by a small additional cost for loading and unloading and a trifling longer delay in port.

About 30% of the freight traffic is carried by vessels capable of drawing from 23 to 24 ft., and a draft of 21 ft. could be used by vessels carrying 95% of the freight. With the present fleet it is estimated that a total gain of $15 000 000 per year would result were a 25-ft. channel made available.

To sum up the case for Great Lakes navigation, the savings by this system have piled up a surplus of $2 000 000 000 in the last two decades alone. The savings amount now to $100 000 000 per year. A further saving of $15 000 000 per year awaits the development of deeper channels.

Two fundamental methods present themselves by which deeper channels may be obtained. It is a physical possibility to raise all the lakes by 4 or 5 ft. With comprehensive regulation, meaning thereby control of river slopes as well as of lake levels, the deeper channels would result. If this were attempted and the St. Lawrence outflow entirely cut off, it would take about 20 months to accomplish the initial rise. If the St. Lawrence flow were reduced 20%, it would take 8 years. This plan, however, is manifestly impracticable as resulting land damages would be too great, and the value of existing port facilities would be almost entirely sacrificed.

The second method is the excavation of channels to the required depth wherever this depth does not naturally exist. The author suggests a combination of these two methods, which may be referred to as a third plan. The advisability of such a combination will hardly be disputed, although the question as to the extent to which one or the other fundamental method should be applied is one on which opinions will differ, and which merits discussion.

It will be well first to get a clear understanding of some physical facts concerning the Great Lakes—facts which are not always correctly stated and used in discussions of the hydraulics and hydrology of this great reservoir system. The fact that the water levels of the Great Lakes are now comparatively low, especially on Michigan-Huron with its thousands of miles of shore line, has attracted wide attention, and has led to much speculation regarding the cause, particularly among laymen. Having available definite gauge readings on each lake extending back to 1860, the extent of this lowering may be determined, and it appears that the average level for 30 years (1890-1919), is below the level of the preceding 30 years (1860-1889), by the following amounts for the several lakes: Superior, 1 in.; Michigan-Huron, 17 in.; Erie, 9½ in.; and Ontario, 8 in. For the last four years the supply has been unusually deficient; in fact, on some of the lakes deficient to an unprecedented degree for so long a period. Compared with the 60-year mean (1860-1919), the average level for 4 years (1920-1923), has been low by 2½ in. on Lake Superior, 15 in. on Lake Michigan-Huron, 7½ in. on Lake Erie, and nearly 9 in. on Lake Ontario.

Based on the discharge values of the St. Lawrence River given in the 1921 Report of the United States and Canadian Government engineers on the St.

Lawrence improvement for the years, 1860-1887, and the discharge values as determined by the U. S. Lake Survey for subsequent years, it appears that the supply to the water surface of all the lakes for the 30 years, 1890-1919, was 5.5 ft. less than for the 30 years, 1860-1889; or, in other words, that the average shortage in supply for the later 30 years was about 2¼ in. per year. This represents a decrease in supply of about 6 per cent. To indicate the proportion of this deficiency in supply for which Lake Superior is accountable, by comparing the two 30-year periods, the net supply for the later 30 years is found to be lower by 10.9 ft., or the equivalent of 3.6 ft. on the surface of all the lakes. Thus, two-thirds of the total shortage of 5.5 ft. is found on Lake Superior, although the area of its surface is only one-third of the total area of all the lakes. Accordingly, the intensity of shortage on Lake Superior was double that on the other lakes. With this proportion of the lack of supply in recent years attributable to Lake Superior, it is interesting to consider why the average level of Lake Superior was lowered only 1 in. and that of Lake Erie only 9½ in., while the average level of Lake Michigan-Huron was lowered 17 in.

As to Lake Superior, its level was interfered with by various changes in the outlet. The first obstruction took place about 1887 when bridge piers were built near the head of the Rapids and certain small channels were shut off. This occurred near the close of the first 30-year period of record. Other encroachments followed, modifying the equation of flow, and about 1900 the use of water in side outlets for water power began, but was partly or fully compensated by obstructions. Later, the compensating or regulating works were built, and since 1921 complete control of the outflow has been possible.

By the use of these regulating works, the level of Lake Superior has been held up, the present level being about 1 ft. higher than it would have been had the outlet remained in its original condition with no water used, for power or otherwise, in side canals. It should be noted that this result was accomplished in spite of the fact that the intensity of depleted supply was highest on Lake Superior. Had the restrained water making up this 1 ft. of storage been allowed to discharge gradually in accordance with the original conditions of the outlet, it would have raised the lower lakes a small amount, not, of course, in proportion to the areas, because the discharge of each outlet would have been increased.

A rather definite part of the depression in level of Lake Michigan-Huron in the later 30 years is due to the diversion through the Chicago Drainage Canal; but this diversion affects also Lakes Erie and Ontario. The discrepancy of about 8 in. between the average lowering of Lake Michigan-Huron and that of Lakes Erie and Ontario thus remains to be explained. This apparent discrepancy has sometimes been attributed to scour or to the excavation of navigation channels in the outlet of Lake Michigan-Huron, particularly in the Detroit River. The Board of Engineers on Deep Waterways concluded that scour had taken place at the head of St. Clair River, but comparison of surveys made by the speaker with an old map of 1857 gave no evidence of such a change.

Theoretical calculations indicate that the necessary fall in this connecting channel has not been reduced by channel improvements more than 2 or 3 in. In this connection it should not be overlooked that the improvement of a given reach of channel cannot reduce the fall in the reaches above and below. If in a channel 80 miles long, with a uniform slope and a fall of 8 ft., a reach of 5 miles is so improved as to make it practically a lake, the total fall cannot be reduced more than 6 in. It should also be considered that in dredging operations the material usually is put back in the original river channel, and that it easily may be so placed as to maintain the original slope.

Passing to practical considerations, there exists in the channel connecting Lakes Huron and Erie an enlargement called Lake St. Clair, the level of which, at least in the summer months, is controlled by the levels of the two larger lakes. The level of Lake St. Clair during ice-free months can be expressed by a formula making it a function of the levels of the upper and lower lakes. This formula holds good with residuals of 0.1 ft. or less for 40 years, except for short periods when known obstructions were temporarily in place. There is, therefore, practically no evidence of such a change in the channel as to indicate a reduction of slope between Lake Huron and Lake Erie.

The explanation of this apparent discrepancy in relative water levels of Lake Huron and Lake Erie was investigated by the speaker years ago and the results are shown in his report on the discharge of the St. Clair River made in 1902.* During the winter months the outflow from Lake Michigan-Huron is reduced by the action of ice in the St. Clair and Detroit Rivers. An ice cover usually forms over a considerable portion of this connecting channel, which reduces the discharge according to the laws of flow, but a much greater effect results from ice jams that occur at times, especially in the St. Clair River.

This ice effect was evaluated by discharge measurements taken from January to April, 1901, which showed individual determinations as low as 75 000 cu. ft. per sec., or considerably less than one-half the normal discharge. Connecting these discharge measurements with the readings of gauges established in 1899 at the head of the river resulted in an equation for winter discharge from which it appeared that for the three winters, 1901-03, there was an average reduction in flow of 50 000 cu. ft. per sec. for 4 months of each winter, equivalent to about 0.41 ft. per year on the surface of Lake Michigan-Huron. It is apparent that variations in this ice effect are sufficient to account for temporary changes in the relative levels of Lake Michigan-Huron and Lake Erie.

The gauges at the head of the St. Clair River have been maintained since 1900, but there is no reliable method of determining the winter discharge prior to that date. The effect of ice varies from year to year according to the severity of the winter, not following closely the mean temperature, but probably dependent on the number of short periods of extreme cold followed by temporary break-ups.

* Report, Chf. of Engrs., U. S. Army, 1902, p. 2825.

The speaker's explanation of this discrepancy in the levels of Lake Huron and Lake Erie is that the average ice effect in the earlier 30 years of record, which cannot now be evaluated, was greater than that of the later 30 years. This cannot be definitely proved, but some light can be thrown on it by a consideration of the indicated local supply to Lake Michigan-Huron for 60 years. The local supply to any lake is determined by adding the discharge to the storage and subtracting the inflow. The inflow to Lake Michigan-Huron from Lake Superior is known in winter nearly as well as in summer; but in determining the outflow from Lake Michigan-Huron prior to 1900 the figures for discharge for the ice period are generally too high, and accordingly give too high a local supply for the winter months.

A comparison of the net local supply to Lake Michigan-Huron for the 40 years, 1860-1899, with that for the 20 years, 1900-1919, shows the indicated net supply for the former period to average 3.036 ft. per year and for the later 20-year period, 2.816 ft., indicating a shortage in net supply of 0.22 ft. per year.

This retardation by ice, however, occurs entirely in the half year from December to May, inclusive. Dividing the yearly supply into two parts, the period from December to May being called the first half year and that from June to November the second half year, it appears that for the earlier period of 40 years the net local supply to Lake Michigan-Huron averaged 2.071 ft. in the first half and 0.965 ft. for the second half. Of the later 20-year period, 1900 to 1919, inclusive, there is a fair knowledge of the winter discharge. This shows the net local supply to average 1.712 ft. per year in the first half and 1.104 ft. per year in the second half. Therefore, while the average supply for the second half of each year during the later 20-year period actually exceeds that of the corresponding half of the year for the earlier period by 0.14 ft., the average supply for the first half of the year for the later 20 years is 0.36 ft. less than the indicated supply for the corresponding part of the year in the earlier period.

It is submitted that such a condition is not likely to have occurred and that the figures for the winter discharge of the St. Clair River prior to 1900 are probably too high by from 0.36 ft. to 0.50 ft. The result for 3 years (1900-1902) indicated a reduction of flow equivalent to 0.41 ft., as already mentioned. These results are mutually confirmative. Correcting the years prior to 1900 by 0.41 ft. each, shows the average net supply to Lake Michigan-Huron for the 30 years, 1860-1889, to be 2.74 ft. on the lake surface and for the 30 years, 1890-1919, 2.64 ft., a difference of but 0.1 ft. per year, or less than 4 per cent. Reduced to the area of all the lakes this represents a shortage of only 0.05 ft. per year, or about 1½ per cent.

Briefly then by comparing the record of 30 years (1860-1889) with that of the following 30 years up to 1919 there appears a total shortage in supply to all the lakes of 5.5 ft. in 30 years, an average reduction of 0.18 ft. per year, or 6 per cent. Of this shortage of 5.5 ft. Lake Superior's supply deficiency accounts for 3.6 ft., or 65%, Lake Michigan-Huron's deficiency for 1.5 ft., or 27%, leaving only 0.4 ft., or 8%, to be allocated to Lake Erie and Lake Ontario.

The author, using perhaps different data as to the outflow from Lake Ontario, finds a smaller deficiency in supply, only about 3%; but taking the larger figure of 6%, or 5.5 ft., in 30 years, an average of 2¼ in. per year, is this a sufficient change to warrant the conclusion that the trend is definitely downward, and to launch a discussion of changes in climate, permanently reduced precipitation, and the effect of clearing the forests? The speaker thinks not. On the other hand, he believes that the experience of the past, and particularly of the last three or four years, should not be allowed to pass without profiting by the lesson that natural water levels recede and that to whatever extent they may be artificially sustained, datum planes for improvement should be set low enough to assure continuous maintenance of the navigation depths found to be economically justified. This depth at the present time is considered to be that permitting a draft of not less than 24 ft., which the largest lake carriers are now able to utilize and for which many more would be built within the ten or fifteen years required to make the improvement.

In considering to what extent lake-level regulation may replace the improvement of channels by dredging, it is desirable to state some principles that appear axiomatic regarding the operation of reservoirs. Two of these were well stated by the late General Chittenden, in his paper* on the "Reservoir System of the Great Lakes of the St. Lawrence Basin", as follows:

"I.—The effect of a natural reservoir upon a stream passing through it is to reduce variations and irregularities of flow and to give the stream a more uniform discharge upon leaving the reservoir than it had before entering."

* * * * *

"II.—Any reduction of the normal oscillation of level in a natural reservoir will increase the variation of flow in the outlet; and any reduction of the normal variation of flow in the outlet will increase the oscillation of level in the reservoir."

The effect of a uniform lake level is primarily to retain harbor depths. An incidental effect is the stabilizing of the water level for a certain distance up stream from the mouth of the inlet from the reservoir above. The extent of this latter effect depends on the character of the outlet.

Lake Superior, already under regulation, is admirably adapted to this treatment. The rock rim restraining the lake furnishes excellent foundations, and a ¾-mile reach of rock apron below the works insures against scour from concentrated currents. The natural drop over this rock apron was 17 to 21 ft. The level of Lake Superior either under natural or control conditions is free from any effect of the level of Lake Michigan-Huron, the next reservoir below. The section at the regulating works will always remain in control as the lower river will carry any reasonable discharge without affecting the flow through the works which cannot be drowned out to any extent. On the other hand, the slope in the lower river, to accord with present datum planes, will be maintained by the use of the minimum discharge required for power.

With the proposed improvement of the St. Lawrence similar advantages for regulation will be found. The water levels in the river are seriously affected by ice, but under the suggested arrangements the control works cannot

* *Transactions*, Am. Soc. C. E., Vol. XL (1898), pp. 359 and 365.

be drowned out. When the St. Lawrence is improved for deep navigation these control works will form a part of the plan and the level of Lake Ontario can be regulated. Until the river is so improved, deeper channels below Buffalo are not important.

Turning to Lake Erie, the control of this lake has been the subject of a number of studies, the conclusion usually being favorable with certain limitations. One objection is that if control means a higher average level the occasional storms on Lake Erie would be somewhat more destructive, especially to Buffalo. The principal objection heretofore is that regulation of Lake Erie, without coincident regulation of Lake Ontario, would increase the fluctuations in level of the latter lake, and as concerns the two border countries it happens that the one more interested in the maintenance of levels on one lake is less interested in the maintenance of levels on the other. With the improvement of the St. Lawrence this diversity of interest and its effect would cease.

In the Niagara River the conditions for control are only less favorable than in Lakes Superior and Ontario. Here, again, the ice problem is important, but there need be little fear of the effect of the works being drowned out by the action of the outlet channel below, and if a temporary low controlled discharge depresses the water in the lower river, the effect will not be serious as the navigation there is not important. Accordingly, even if the improvement of the St. Lawrence should be indefinitely postponed, it is thought that the level of Lake Erie should be controlled, but without a radical increase in its mean level, say, within limits of 1½ ft., or at most, 2½ ft.

As regards the outlet of the largest single reservoir in the system, the St. Clair and Detroit Rivers draining Lake Michigan-Huron, this connecting channel is about 80 miles in length with an average fall of only a little more than 0.1 ft. per mile. The bottom in general is gravel, sand, and clay, except for a rock ledge overlaid with boulders near the lower end. In general, the river is about ½ mile wide and, except at and below the rock ledge mentioned, good navigation depths exist naturally; but where the width is increased to ¾ mile, shoals appear. The regimen, now established by the existing discharge with its relatively small variations, is remarkably stable. With a considerably increased flow capacity the new conditions might be less permanent.

In this lake outlet there is a natural controlling works, or perhaps, more properly, compensating works, set up at times by Nature in the form of retardation of flow by ice. As regards levels, the effect of this natural regulation has in general been good. The trouble is that Nature sometimes neglects to apply the remedy. This natural compensation, if made certain, would be ideal in some respects. It does not seriously affect water levels in the outlet. Whatever effect it has is exercised when the only navigation is in light-draft ferryboats. Thus far, it has not seriously affected any power development. It has to some extent depleted the flow over Niagara Falls and thus affected the grandeur of that spectacle, but Lake Erie fills so rapidly in the spring that by June the flow is restored, and no complaints are known to have resulted from this kind of regulation.

In this paper the mass curve is ingeniously applied to the Great Lakes System to show the maximum value of the continuous yield. By taking advan-

tage of whatever diversification in water-sheds may exist and by the use of the mass curve for mean annual yields, the author is able to show a possible increase of 10 000 to 20 000 cu. ft. per sec. of prime water for power.

It is quite proper that a paper on the St. Lawrence development should be written from a water-power point of view; but to secure this additional volume in actual operation is it not necessary to have the omniscience which is assumed in the method adopted in the paper? Knowing what is to take place in the next year, or the next five years, a decision as to the flow to assume for the earlier period is fairly simple. If any rule has been deduced whereby the several works can be operated without this omniscient mind, it does not appear, and the speaker's experience with similar but simpler problems leads him to doubt the equally smooth working of the theory under conditions of stated limits but of uncertain sequence.

Each one of these lake reservoirs has a considerable fluctuation in local supply. There frequently occur monthly maximum supplies of 1 ft. on Lake Ontario, 0.8 ft. on Lake Erie, 0.6 ft. on Lake Michigan-Huron, and 0.5 ft. on Lake Superior. On the other hand, negative supplies, meaning greater evaporation than local supply from the basin, occur almost every year, the values of these negative supplies being not infrequently 0.2 ft. or 0.3 ft. per month on Lakes Ontario and Erie, and 0.1 ft. on Lakes Michigan-Huron and Superior. With variations in local supply amounting to 1 ft. per month, the difficulty of maintaining levels within a total range of 1½ ft. may be seen.

No attempt is made in the paper to follow through the details of regulation, the author contenting himself with a broad presentation of the subject. It is of interest, however, to test the possibilities of regulation under the limits laid down. For the condition obtaining in 1910 and 1911, an attempt to restrain the lakes within these limits by the methods suggested by the author would appear to have required changes from the natural flow volumes of the outlets of from 50 000 to 75 000 cu. ft. per sec. in certain months, and still serious oscillation in the level of Lake Michigan-Huron could not have been prevented, but this level would have had a range of 1.75 ft., while in these two years the level would have fallen nearly 1 ft. below the proposed lower limit. This could not have been corrected by increased discharge from Lake Superior, because for these two years the natural rate of discharge from Lake Superior was reduced by regulation 15 000 cu. ft. per sec. below normal, and yet the lake fell 0.3 ft.

In 1924, the level of Lake Michigan-Huron fell 6 in. with an average discharge of only 152 400 cu. ft. per sec. During the four years, 1920-24, the levels of Lakes Superior and Michigan-Huron were depressed about 1.5 ft., with an average discharge of the St. Clair River of approximately 167 000 cu. ft. per sec. Since no excess supply could have been drawn from Lake Superior, this average discharge of the St. Clair River would seem to be as great as would be available for long periods under similar conditions with complete regulation in effect.

It is fully appreciated that the author is merely sketching works and methods, not specifying details, but the speaker is only attempting to point

out the possibility of disappointment in the working out of details when this becomes necessary.

With Lake Michigan-Huron under complete regulation, throttling the discharge of the St. Clair River at or near its head will at times result in quite serious depression of level below the works. An indication of the extent of this depression appeared in the plan originally proposed by the author which included locks with lifts of from 1 to 5 ft. As finally submitted, however, (Fig. 5), the locks have been replaced by navigable passes combined with expansion basins. With Lake Erie at a regulated stage of 573.0 ft., a fall of only about 6.5 ft. would be required to carry a reduced discharge of 160 000 cu. ft. per sec. through the Lake Michigan-Huron outlet, giving a level of 579.5 ft. at the head of the St. Clair River, or about the present low-water datum. Since it is mainly the connecting channels that are shallow the maintenance of levels in the rivers is more effective in reducing dredging costs than the preservation of the levels of the lakes. Under natural conditions high lake levels result in corresponding channel depths, but, as indicated, this condition easily may be disturbed by the character of regulation suggested for such a channel as the St. Clair River.

The proposed plan contemplates the enlargement of channels to take care of excess flow, the latter being required in order to assure the large prime volume of 230 000 cu. ft. per sec. It should be pointed out that in the case of the Lake Michigan-Huron outlet, 80 miles long, it may prove as much of a task to provide this additional flow capacity by dredging, as to provide by the same method the desired depths for navigation throughout the shorter reaches requiring improvement for this prime purpose.

In this connection, the suggestion that the Chicago Drainage Canal contributes an effective share of this needed additional capacity is not tenable unless it be assumed that the flow through that Canal is subject to regulation. To make this clear it is only necessary to assume the flow in the Chicago Drainage Canal to be, say, 175 000 cu. ft. per sec. There would then be, at times, no flow remaining in the St. Clair River to be regulated. Uncontrolled diversions are serviceable in regulation only when the flow is returned to the main outlet or to a lower reservoir of the system, a condition not applying to the Chicago Drainage Canal.

The value for power of the additional prime water which it is proposed to make available by an elaborate system of regulation, would be more impressive if every means were being taken to permit the use of more power at Niagara while preserving the scenic beauty of the Falls. It would also be more impressive if it was certain that all the water power developable on the St. Lawrence could find a ready market, and if, in the plans proposed, consideration were not being given to the entire omission of power works in an important part of that river.

In computations of power benefits the author seems to use a figure of about $7 per h.p. as the annual value. Assuming a final development of 7 000 000 h.p. on the Niagara and St. Lawrence Rivers combined, would give a total annual value of $50 000 000, or less than one-half the benefits now

resulting from the Great Lakes navigation. The time may come when the power value of this additional water can be fully realized, but this time has not yet arrived. When it does come, the value will still be below that resulting from navigational uses. Certainly to-day and in the immediate future the needs of navigation should not be sacrificed in the name of power. To require vessels to pass through locks at the foot of Lake Huron or to subject them to excessive currents would unquestionably be detrimental to the interests of navigation.

Partial regulation of Lakes Michigan-Huron through works located below the head of the river would seem to fit the present need of control at this point. These works should be located in a wide section of the river, perhaps in the vicinity of Stag Island. Their character should be such that a part of the flow could be restrained during the winter months when this restraint should be needed, while not ordinarily reducing the summer flow nor forming any hindrance to navigation. Works of this character would be operated to restore gradually the mean level of Lake Michigan-Huron, and could form a part of more extended works later should it develop that greater control were desirable and that it could be obtained without introducing other evils.

The author expresses the hope that the subject will provoke discussion. As the paper is general, the discussion must be of a similar character. Having in view particularly the needs of navigation, the speaker feels that its requirements have been subordinated to those of power. That an increase in prime water is given more weight than better continuous navigation depths. The speaker has attempted to bring out the enormous benefits derived now and in the past from navigation on the Great Lakes, indicating a surplus of $2 000 000 000 now standing to its credit, which is being increased at the rate of $100 000 000 per year, and to show that this navigation should be supplied with the 25-ft. depths it now requires for economical operation.

It has been shown that, whereas the present supply to the lakes is low, there is little to indicate that this condition is permanent; nevertheless, that steps should be taken to prevent the recurrence of extreme low water, but that these steps should be such as not to result in destructive levels during periods of high supply. It has been suggested that the control system proposed might be found disappointing in its final analysis and more expensive than present benefit to power would justify.

Finally, the opinion is expressed that the regulation of Lake Erie should be exhaustively studied, and, that if no insurmountable difficulties appear, it should be put in operation; that minor works should be placed at once in the Lake Michigan-Huron outlet, and that a program for depth betterment to the extent of 25-ft. channels on the Great Lakes should be immediately adopted and entered upon. Such a program would require fifteen years for its consummation. By that time control would have had its preliminary trial, power needs would have increased and presumably would have been supplied either at Niagara or on the St. Lawrence, or both, and during this process, by proper allocation of work on the navigation project, navigation benefits would have been progressively obtained.

GARDNER S. WILLIAMS,* M. AM. SOC. C. E.—The speaker is in harmony with the general expressions which have been made in the discussion of the Great Lakes-St. Lawrence Waterway. Referring to the remarks of Mr. Sabin, however, he would call attention to certain historical facts. The early explorers coming up the channels connecting the Great Lakes reported that those channels varied in depth from 8 to 12 ft. Mr. Sabin has stated that there is now a 21-ft. channel through the same reaches. Students of hydraulics can readily decide whether the deepening of channels that were between 8 and 12 ft. to 21 ft. in depth has or has not enabled more water to flow out of the upper into the lower lakes.

Attention is directed to the program which was recommended in the report on the St. Lawrence Waterway submitted to the International Joint Commission regarding the development of that section of the river below the International Boundary. As stated in the paper, that program contemplates by-passing the traffic through 28 miles of canal and 5 locks, counting the twin locks as one. It contemplates no power development within that reach, although there are about 2 000 000 potential h.p., and is estimated to cost $92 000 000.

It has been intimated that the reason the Commission adopted its method of treatment of this section of the river was the belief that there was not a market available for that amount of power in connection with what would come from the upper reach. In that same report, however, the Commission estimated the horse-power demanded within 300 miles of the Long Sault to be 13 350 000 e. h. p. in 1925, for the United States and Canada, and, in 1930, 15 375 000 e. h. p. is estimated, or an increase in 5 years of 3 025 000 e. h. p.†

The contemplated works will not be built in five years. If the estimated rate of increase of power demand continues, according to the Commission's own figures, that power would all be absorbed as soon as it could be put upon the wires. Referring now to the super-power report, which was an investigation of the demands for power in the region of the United States from Washington, D. C., on the south to Boston, Mass., on the north, the central part of this zone is within reach of the St. Lawrence power.‡ That report states§ that the energy economically to be taken from the super-power system in New England and New York and Upper New Jersey—all of which territory is within 300 miles of the generating points of the possible power developments of the Great Lakes-St. Lawrence Waterway—in 1930 from new sources will be 2 232 000 e. h. p.; that is, it is estimated that in 1930 there will be needed from a super-power system in this district new power to the extent of 2 232 000 e. h. p. It was further estimated by the Super-Power Commission, that the increase in steam-generated power in the area noted, from 1919 to 1930, would be 2 059 000 e. h. p.‖ That is about all the St. Lawrence River would yield if distributed over the wire, into that territory. It appears, therefore, that

‡ "A Superpower System for the Region between Boston and Washington," by W. H. Murray and others, *Professional Paper No. 123*, U. S. Geological Survey, 1921.

§ *Loc. cit.*, p. 181.

‖ *Loc. cit.*, pp. 160–161.

the idea that there is no use for the power—that it is not needed, and could not be disposed of—is a mistake.

The development of this water power will be a source of revenue to Canada, and a source of revenue, through sub-station service, to the people of the United States.

There is, however, another element involved. The people in the Central States are not very much interested primarily in the development of water power to be used in New England and Northern New York; but a certain amount of power is to be absorbed in that territory, and whether it comes from the St. Lawrence and Niagara Rivers, or from the burning of coal, will make no difference. The power will be utilized. Now, if that power does not come from the St. Lawrence River, or from the Niagara River, and some minor water-power sources that are hardly worthy of consideration in connection with them, it will have to come from coal. The amount of fuel consumed by public service corporations in New England, New York, and the northeastern part of Pennsylvania, for 1919 was more than 11 000 000 tons of coal; or, more accurately, it was equivalent to more than 11 000 000 tons of coal. Some of this fuel was oil and some of it was gas; but the bulk of it was coal. The coal used by public service corporations in the States of Illinois, Indiana, Ohio, Michigan, Minnesota, and Wisconsin for the same period was about 10 700 000 tons.* In other words, if sufficient St. Lawrence power went over into New England, New York, and Northeastern Pennsylvania to replace the coal that is now burned by the public utilities in that district, there would be sufficient coal released to supply the public utilities in the States of Illinois, Indiana, Ohio, Minnesota, Wisconsin, and Michigan, and that is why the people of the Central States are interested in the utilization of St. Lawrence power in New England and New York.

Simply as a matter of comparison, the total output of fuel for the United States is the equivalent of about 600 000 000 tons of coal per year; and the railroads use 180 000 000 tons. The Super-Power Commission previously referred to, in investigating the cost of the operation of railroads by means of central stations and electrical locomotives, showed that nearly 75% of the fuel burned by the railroads could be saved if they were operated from central generating steam stations.† If the railroads in this district are supplied with electricity generated by water power, there will result a further saving, which becomes of interest.

Turning now to another phase of the subject, it has been stated that the estimates for this project were probably inadequate. The speaker most fully concurs in that opinion. He has taken some pains to compare the costs of similar works where such have been built under the direction of the Corps of Engineers of the United States Army as far as similar work can be found, and from the records, his estimate, or his guess, is that the cost of this development, including the water power features, will be more nearly $600 000 000 than $500 000 000, which latter sum is about twice as much as the last report indicated would be involved.

* U. S. Geological Survey, Monthly Reports of Fuel Consumption.

† Super-Power Report, *Professional Paper No. 123*, U. S. Geological Survey, p. 62.

Opinions have been expressed as to whether water power should build this waterway, or whether water power should be subsidized, or whether water power should be considered at all, or whether navigation should be considered at all, and perhaps the speaker may also be permitted to express an opinion, that is, the water power of the St. Lawrence River is needed now, and can be absorbed as soon as it can be put upon the wires. The water power development of the St. Lawrence River will provide almost everything that navigation needs except the locks and the deepening of the channels at the upper ends of the pools. Therefore, let the water power interests build the dams and develop the water power as fast as they will, under the most liberal terms that the Governments can grant them, and let the Governments provide the cost of constructing that part of the work which is necessary for navigation. If the problem is developed in that way, the burden will not be so great but that Canada, even with the enormous load that she is carrying, can take a reasonable share in this project. The people of the United States can hardly realize what conditions must be across the border, but if they examine the expenditures of Canada during the World War, and the vast projects in public works which Canada has been carrying on, they cannot blame her for hesitating to bind herself at this time to the expenditure involved in the development of the St. Lawrence Waterway. If that cost can be put where those who will profit the most by it can bear it, however, the cost will be reduced, as far as the Governments are concerned, to a figure that seems to be entirely within their reach.

Next to the Great Lakes-St. Lawrence Waterway, there is no subject before the people of the United States to-day about which a greater amount of misinformation has been disseminated than the so-called Chicago Drainage Canal, and although the Canadian Government—and this is said not in any spirit of antagonism or of criticism—is demanding, or at least suggesting, that the Chicago diversion be prohibited or restricted, attention should be called to the fact that in a treaty which now exists between the United States and Great Britain, covering the use of the boundary waters, there is a provision that the Dominion of Canada may have 16 000 cu. ft. per sec. more water to use at Niagara than the United States. If one will go back to the records, and those records are in Canadian publications, it will be found that such allowance was made to compensate Canada for a diversion supposed to be 10 000 cu. ft. per sec. at Chicago.

Attention may also be called to the fact that, whatever the effect of a diversion of 10 000 cu. ft. per sec. on the navigable depths of the Great Lakes may be, the proposed diversion of approximately 15 000 cu. ft. per sec. through the Chippawa Canal, around Niagara Falls, if uncompensated, will lower Lake Erie by approximately 50% more than the diversion at Chicago; and that the lowering of Lake Erie will be accompanied by a lowering of Lake St. Clair and the Detroit River, of approximately the same amount as that due to the Chicago diversion, and by a lowering of Lakes Michigan and Huron by approximately one-half the latter amount. Attention is further called to the fact that Canada is diverting about twice as much water through the Welland

Canal at present as was so diverted prior to the World War. When Canada contends that the diversion at Chicago is lowering the Great Lakes, and wants it stopped, it may be proper to suggest that consideration be given to the effect of its own diversions on the levels of Lake Erie and the Upper Lakes.

The speaker does not oppose diversions of water through the Canadian developments for water power below Niagara. He considers it more economical to take that water through the Queenston-Chippawa Canal to utilize the large head that is possible by obtaining it near Lake Ontario, than to take it at the Falls and derive only one-half the power. He is in favor of all that, but let there be fairness to all sides.

E. P. Goodrich,* M. Am. Soc. C. E.—It is obvious that Government expenses for deeper waterways and for harbor improvements are subsidies of one kind or another. The speaker would suggest another kind of subsidy for consideration at least by the present International Joint Commission, and possibly by the board or commission which Mr. Parsons has suggested might be appointed as an auxiliary investigating body. This alternative is a railroad subsidy to cover what might be called full train operation through from origin on one of the Great Lakes ports to some seacoast port, on an export tariff basis. It might be handled, for example, by a Federal commission, like the Wheat Commission, which would provide funds for by-passing the congested railroad throats on the railroad systems, as they exist to-day, so that the operation of a through train could be expedited and thereby decrease the time required of freight cars, the extra return accruing to the railroads, which, in their turn, could distribute this saving, at least in part, to the shippers through a lowered export rate.

Certain investigations made in connection with the project for deepening the Upper Hudson to provide a Troy-Albany Port gave statistics which may be of interest in this connection. The present probable total export Gulf and Pacific commerce, to and from the district that was tributary to the St. Lawrence, as well as to the Upper Hudson port, was carefully estimated on several bases. A figure of 15 000 000 tons per annum, as a total of all types, was finally reached. Obviously, a ship will not come inland, making a special trip, unless it can have a large proportion of its cargo assured. In other words, there must be facilities at any lake port for collecting tonnage of a considerable amount destined for one or perhaps a group of foreign ports, so that the vessel can have sufficient inducement to make the trip. Studies were made to determine as to what commodities and in what quantities there was sufficient inbound and outbound tonnage to induce a vessel to make such a trip, at least as far as the Upper Hudson port. It was calculated that a tonnage not to exceed 5 000 000 would be thus available, and that there might be diverted additional tonnage not to exceed 1 500 000, with a possible increase to 5 000 000 in the course of the next decade, estimating on the rate of growth which has taken place in the Panama Canal, and other ship canals, and harbors in various parts of the world.

* Cons. Engr., New York, N. Y.

It may be of interest to discuss the eventual tonnage which may be derived in that way. Working on the basis of population estimates of the United States as a whole, and the proportion which it is expected will find itself in the tributary area of the hinterland of the St. Lawrence, say, 100 years hence, and basing these estimates on studies by Professors R. Pearl* and E. W. East,† and by the speaker,‡ it is probable that three times as much tonnage will be found available in the next 100 years. Assuming 6 000 000 tons per year, and 40 tons per car, this gives 150 000 cars per year; and assuming a 1 200-mile haul, at 4 miles per hour, 300 hours will be required. If by means of detours around traffic throats and the same methods of operation used to expedite freight as are common in expediting through traffic across the continent, for example, with reference to passenger trains, this time were to be cut in half so that an average speed of 8 miles per hour were secured, a saving of 150 hours, or 22 500 000 car-days would be made. At $1 per day, which is the usual rate, there is obviously an annual saving of $22 500 000, simply in the use of cars. Capitalizing this, and assuming that $5 000 000 is required for each throat to provide facilities to expedite travel, there still remains a saving of $162 000 000, capitalized, or $8 100 000 per year. On the basis of the 6 000 000 tons assumed, there is an immediate saving indicated of $1.35 per ton, which might be returned directly to the farmers in their shipment of grain, or to other shippers and receivers of freight, provided the plan suggested could be put into effect.

The speaker does not wish to be misunderstood as making this suggestion with reference to railroad operation. He has long been interested in the development of water terminals and waterways and believes that, eventually, the St. Lawrence project may be economically feasible, but it is obviously unwise for the two countries as a whole to expend moneys for waterways if the capital already invested in railroads might be used possibly to better advantage.

The paper is of considerable interest because it points out some of the things which have not heretofore been discussed, and the author is to be complimented for providing the opportunity to discuss these various details.

David B. Rushmore,§ M. Am. Soc. C. E.—Although forecasting economic and social conditions is only an approximation, it is certain that by the time hydro-electric development in connection with the St. Lawrence Ship Canal can possibly be completed, all the electric power produced can easily be consumed, if less than one-half of it in Canada, surely much more than one-half on the American side. There is no engineering difficulty of great magnitude in connection with the design of the power-house, of transmission systems, or of the distribution and use of this power. What is lacking is an understanding and an appreciation on the part of the average citizen of New England, New York, New Jersey, and Pennsylvania—the situation dis-

§ New York, N. Y.

cussed so well by Mr. Gardner S. Williams—of the benefits to be received by this power.

There is no man who, if he saw a coal mine on fire, would not endeavor to put it out, or to stimulate the efforts of those responsible for the fire to extinguish it. Wherever water power remains undeveloped, within reach of markets that are burning fuel, as at Niagara Falls and on the St. Lawrence, there is a coal mine on fire. At the World Power Conference, held in London, England, in July, 1924, one of the most striking features brought out was the many ways in which the people, through the Governments, are co-operating with the people as organized through private corporations. The great expenses necessary for the St. Lawrence investigation were contributed by people interested, who felt that it would be desirable to consider all its possibilities and that some satisfactory way should be evolved whereby the Government and private parties could co-operate to a satisfactory outcome.

Consider the demand for greater publicity; incidentally, that is one thing that can be done by the members of the Society. The great benefit from presenting such an interesting paper is that the public can be educated regarding the engineering facts and economic benefits to be received. Then there is a demand for a new kind of engineering—a presentation of engineering facts with as accurate a forecast of the economic and social conditions as possible, and a design of the project that is going to bring together and harmonize all the elements involved and that will permit in a reasonably short time of carrying this great project through to completion.

Maurice W. Williams,* M. Am. Soc. C. E.—Reference has been made to the diversion of water from Lake Erie through the Welland Canal as being greater in quantity than certain other amounts which are diverted into avenues lying wholly within the United States, such as the Chicago Drainage Canal. The Welland Canal simply happens to lie in Canadian territory, but is open to the free use of the vessels of both countries. That being the case, certainly Canada cannot properly be charged with the total quantity of water used in the Welland Canal. It may very properly object to the diversion of water for the use of any municipality in the United States, however desirable such diversion may appear to that municipality, the more so as all water passing through the Welland Canal is retained within the St. Lawrence drainage area while all water diverted through the Chicago Drainage Canal is permanently lost to the St. Lawrence.

L. H. Hart,† Esq.—The speaker heartily agrees with the great majority of those who are discussing the St. Lawrence Waterway project, that it is inevitable. He wishes, however, to summarize briefly the reasons why the money should not be spent during the lifetime of this generation. All these reasons fall under the general head of putting first things first.

On the navigation side of the question, the control works mentioned by Mr. Shenehon needed to raise and stabilize the lake levels, and the deepening of harbors and channels, are essential to the general plan. Let them be con-

* Cons. Engr., New York, N. Y.
† Buffalo, N. Y.

structed first, as they are within the United States and will be worth many times their cost, whether or not the St. Lawrence River in Canada is developed. Let full use also be made of the existing 14-ft. canals in the St. Lawrence, the Ohio, and the Mississippi Rivers, and of the 12-ft. canal from Buffalo to New York. New York State has contributed this 12-ft. channel to the National welfare free, at a cost of $200 000 000. Many residents of the State feel that before they are asked to pay a heavy tax for new plans, the existing one should be given a trial. Some feel that the cities of Toronto, Quebec, and Montreal, would be benefited by the St. Lawrence plan, at the expense of American taxpayers, and that it would withdraw commerce from cities in New York State. The speaker does not hold this view.

At present, the bulk of traffic leaving the Great Lakes goes, not to Europe, but to the New York District. The St. Lawrence Channel and the New York State Barge Canal are now being used to only a very small fraction of their capacity. The tonnage which goes from the Great Lakes Districts to Europe could easily be carried on the New York State Barge Canal, even if it is only 12 ft. deep. In short, the time would not seem to be ripe for spending American money for improvements in any foreign country. It should be noted that six of the nine locks which are proposed on the St. Lawrence are entirely within Canadian territory.

Relative to the power side of the question: Before developing power in Canada, let full use be made of Niagara Falls. Only one-fourth of the possible power output is being developed there. The obstacle is that the scenic effect might be marred. The proposed control works, however, could easily regulate and distribute the flow, so that no beauty will be lost. At present, $100 worth of water is wasted for every visitor who enjoys Niagara. The Lower Niagara River in the Gorge is merely awaiting capital for its development. The possibilities there are very great, in comparison with those on the St. Lawrence River. There are also great possibilities in the super-power project and in the proposition to burn coal at the mouth of the mine. These are strictly American, and of known value.

The wisdom of developing power before the market is in plain sight is very questionable, even for a wealthy Government Treasury. The Muscle Shoals Project, almost completed at a cost of $100 000 000, goes begging for lack of a bid of more than $5 000 000. If, as Mr. F. P. Williams claims, the power industries can subsidize navigation, American and Canadian power interests will be willing to do it on their own account.

A. Lindblad,* Esq.—The speaker is not a civil engineer and thus is not handicapped by any knowledge of the engineering difficulties in developing this inland waterway for navigation purposes. He will discuss this project, therefore, only from the standpoint of its shipping possibilities.

Several statements have been made regarding the kind of ships that can be used. In his discussion, Professor Sadler made this point clear, when he stated that he would never expect large ocean-going vessels of the passenger type to come to the Great Lakes. Such vessels are not wanted there;

* Prof., Dept. of Naval Architecture, Univ. of Michigan, Ann Arbor, Mich.

but the Great Lakes should be connected with salt water, so that all those vessels which do not have too large a draft can come to the lakes. There is no need of constructing new vessels. If a depth of 25 ft. is obtained in the channels, that is sufficient to permit approximately 70% of the world's tonnage to enter; and if that depth is increased to 28 ft., practically all ordinary cargo vessels will have access to the Great Lakes.

It has been stated that the cost of ocean-going tonnage is at present two or three times the cost of tonnage on the Great Lakes. That is really not correct. That it is about one and one-half times that cost would probably be a safer statement. Mr. Parsons also stated that the cost of running ocean-going vessels on the Great Lakes would be too great, partly because the vessels were more expensive in first cost, owing to the need of a surface condenser, etc., and partly because they need a larger crew than the lake freighters. It is true that they need surface condensers, but fitting a surface condenser instead of a jet condenser is really a rather small item compared with the cost of other parts of the machinery, and does not add much to the first cost. It is also true that there is a small increase in the numbers of the crew on ocean-going vessels as compared with lake boats. In other words, the cost of running ocean-going vessels is somewhat greater than the cost of running the present lake freighters, but that does not justify the statement that it would be uneconomical to use ocean-going vessels in combined lake-and-ocean traffic.

To obtain the full benefit of a deeper channel it is, of course, necessary also to have increased depth in the Great Lakes ports; but the cost of deepening these ports is not so enormously large as some people would imply. It must be remembered that the shipping on the Great Lakes is not evenly divided among the lakes, but is concentrated and handled at only a few ports. To deepen these ports to about, say, 25 ft., will not, in the speaker's opinion, be such an enormously costly undertaking.

In opposition to the St. Lawrence Waterway project, it has also been stated that it was not practical because it could provide for navigation during only for seven to eight months of the year. Everybody connected with shipping knows that a very large part of the world's commerce is seasonal, and the speaker believes that certainly the largest part of manufactured products could be handled easily in a navigation season of seven months. Consider a parallel from Europe. The whole region around the Baltic, including Sweden, Finland, Russia, Germany, and the new countries like Poland and Esthonia, have to be satisfied with approximately eight or nine months of navigation. Nevertheless, all these countries have been able to develop quite a foreign trade. The speaker thinks that it is an absolute mistake to say that shippers necessarily must depend on twelve months of navigation.

It has also been said, that ocean-going vessels coming to the Great Lakes would not be able to use the present terminal facilities. The grain elevators in particular are said to be suited only for lake ships and would need to be changed. That is another incorrect statement. It is true that ocean-going vessels are not constructed, like the lake freighters, with a very large number of short hatches spaced 12 ft., center to center, which hatches fit the 12-ft.

spacing of the loading spouts of the grain elevators. It is not necessary to be able to load through all the loading spouts. Only those spouts which fit the hatch arrangement of an ocean-going ship need be lowered and used. It is hard for the speaker to believe that any greater changes are needed than to increase the draft at the elevators. The other changes are unimportant.

In discussions of the St. Lawrence Waterway, the speaker has heard a great many statements to the effect that salt-water vessels would not be able to navigate on the Great Lakes, but he has not yet been able to find a naval architect or a marine engineer who said so.

WALTER M. SMITH,* M. AM. SOC. C. E.—The diversion of water at Chicago has little bearing on the St. Lawrence Waterway.

Three days during the past year (1925), the water flowing through the Chicago River and the Drainage Canal has been turned back into Lake Michigan because of heavy rainfalls. Generally, an increase in the number of typhoid fever cases occurred in the neighborhoods supplied by the water. The first case, which occurred in the spring, was at the mouth of the Calumet River. Before the Health Commissioner could issue orders to boil all the water drawn from the crib located nearest this point, the damage had been done. The boiling had to be continued for about two weeks, just because of only a few hours' change in the direction of the flow of the river. Later, there was a very heavy rainstorm in the center of the city, and the flow of the Chicago River again was reversed, this time for about six hours. Immediately, similar orders went out as to boiling the contaminated water. As a rule, people observe these directions rigorously because they know the danger. If Chicago should be deprived of the use of this lake water, the city could not exist for very long. It would have to be abandoned, temporarily at least.

The City of Chicago is now building sewage purification plants as rapidly as they can be constructed. Possibly, engineers are not familiar with the fact that many of these plants are already in existence. It is hoped to build them with sufficient speed so that it will never be necessary to divert more than 10 000 cu. ft. per sec. from the lake. Several years ago when the question of diversion was under discussion, the International Waterways Commission wanted to give the City of Chicago the right to divert 10 000 cu. ft. per sec., and it so recommended. Some of the representatives of the United States and of Chicago objected at that time, because they thought it might be necessary to use more than this in the future, and they did not want such limitation written into the treaty.

The discussion of this paper, with one exception, has been entirely on the question of the profit of building the St. Lawrence Canal from the standpoints of navigation and of water power. Engineers, however, should take a broader view of this subject, and realize that they are dealing with the lives and the property of 3 000 000 people in the question of the diversion of this water from Lake Michigan. It is more than a financial matter. Lake Michigan is an American lake. There is not one drop of water entering it that comes

* Chf. Designing Engr., Div. of Waterways, Dept. of Purchases and Constr., State of Illinois, Chicago, Ill.

from Canadian soil. All the other lakes are along the boundary line, midway between the two countries.

It seems to the speaker that if the question were submitted to an International Court of Law, the decision would be that the United States Government could divert any quantity of water that it cared to from Lake Michigan, without reference to Canada.

There is still another problem for the City of Chicago in the diversion of lake water. When this question first was agitated, the State of Illinois thought that it was the only party concerned, and that neither Canada nor the United States at large had anything to do with it. For a long time this view seemed to be accepted. The State of Illinois, before it would allow Chicago to divert water and reverse the flow of the Chicago River, passed a law that it must divert 3.33 cu. ft. per sec. per 1 000 of population. Now, if Chicago complies with the State law, it must take about 10 000 cu. ft. per sec. from the lake; if it is limited to the quantity allocated by the United States, it may take only 4 167 cu. ft. per sec. The city must break one of the laws.

W. M. Black,* M. Am. Soc. C. E. (by letter).—This paper and its discussions give many interesting and more or less well-founded figures of costs and of expected benefits. They also show the marked diversity of conclusions reached.

The entire subject is being re-investigated by an able board of American and Canadian engineers. Doubtless its report, when submitted, will contain data which will be as full and exact as are now obtainable. The writer believes that it would be wise to await the publication of that report before attempting to form definite judgments on the many controversial questions involved.

As stated by Mr. Sabin, the commerce of the Great Lakes causes for the people of the United States a saving of $100 000 000 annually in transportation costs. If the contention that the proposed deeper St. Lawrence Waterway would result in similar transportation economies is well founded, the desirability of the improvement is established—provided the net cost of making the improvement is not too great.

In general terms it is proposed to regulate the lake flow by suitable works and to concentrate the general slope of the St. Lawrence River into a series of falls, by means of dams, causing an increase of navigable depth in the pools above the dams and utilizing the head formed at the dams for the production of power. In certain localities, where the pool depths are insufficient, side channels are proposed for navigation. It is manifest that, within certain natural limits, the higher the dams, the greater their cost as balanced against the deeper navigable channels of the pools and the greater possible power production.

It is admitted that there is an immediate market for additional power. The question of how quickly an increase of power to the full potential of the fall of the St. Lawrence could be sold is as yet unsettled, and is dependent in

* Major-General, U. S. A. (*Retired*); Cons. Engr. (Black, McKenney & Stewart), Washington, D. C.

a measure on the cost. This, in turn, is a function of the depth of the navigable channel desired.

In so far as is known to the writer all the projects submitted have had for an object the provision of a navigable channel of a definite capacity, with a corresponding power development. Opinions differ as to the channel capacity required. The project depths considered have been 25 and 30 ft. It has been claimed that 25 ft. is an uneconomical depth for ocean carriers and *per contra* the claim is made that there would not be sufficient commerce to justify the cost of a 30-ft. improvement.

A study of this shipping question will disclose the following facts:

1.—For long voyages, when cargoes are available, the greater the cargo capacity of the ship, the less will be the cost per ton of transportation. It is due to this that the average tonnage of both ocean and lake vessels under construction has increased from year to year, and that the relative number of ships of small tonnage is growing less.

2.—For a given tonnage, and within proper limits, an increase of draft provides for a stronger and more seaworthy ship than an increase of beam. Structurally, the ship resembles a truss in this respect.

3.—The strains to which a ship is subject are much greater on the ocean than on the Great Lakes. Lake vessels can be built more lightly, and, consequently, more cheaply, than those designed for ocean navigation.

4.—The ship's complement of men as required by law is greater for the ocean than for the lake carriers.

5.—The draft of the ship is somewhat greater in fresh water than in salt water. For example, a 10 000 dead weight ton cargo steamer which draws, loaded, 27 ft. 2.75 in. in salt water, will have a draft of 27 ft. 6.2 in. in fresh water, or, in other words, with the same draft she can carry 161.5 long tons of cargo less in fresh than in salt water.

For the foregoing reasons transportation costs for a lake carrier in the lakes and in the Upper St. Lawrence River will always be less than for an ocean carrier in the same waters. *Per contra,* ocean carriers of larger tonnage, drawing from 26 ft. to 30 ft. are, to-day, the most economical means of transportation in the ocean highways.

It is claimed that a ship can be designed and built which will be equally good in the lakes and on the ocean. To the writer this seems doubtful. The conditions of navigation differ too widely. Certainly, a channel depth of more than 25 ft. would be necessary for a long-voyage ocean carrier. Such a depth would require expensive and extensive changes in the lake harbors and channels, as well as expensive works in the St. Lawrence River.

There exists to-day an established and efficient freight service between the interior of the United States and its Atlantic seaboard and, *via* the seaboard ports, with all parts of the world. Traders are conservative and a change of trade routes can be established only when the new routes offer positive and marked economies. Witness the slow growth of the Panama Canal traffic where the canal route provides enormous economies in time and costs! To make a deeper St. Lawrence Waterway a great trade highway, the saving resulting from its use must be manifest and marked.

In considering the project for a deeper St. Lawrence Waterway, the liabilities are (1) the first cost, and (2) the cost of operation and maintenance; the assets are (1) the power produced, and (2) the savings resulting from a lessened transportation cost for traffic between the interior, the Atlantic seaboard, and the world at large. The costs to the people of the United States and Canada must be weighed against the benefits to be received. The cost items can be estimated closely; the items of benefit do not admit of exact calculation.

Under these conditions would it not be well to advance slowly? Cannot a project be formed which will permit a progressive development, limiting the works to be constructed at first to those necessary to constitute a fair test of the economic advisability of the entire plan?

The experiment of connecting the lake cities with the Port of Montreal by a line of boats through the St. Lawrence has been tried. The limited channel capacity, however, requires boats that are too small to provide the economic transportation necessary to enable the fixing of the combined lake, river, and ocean freight rates, including transfer charges at Montreal, at a figure enough below the existing rates (by rail to the seaboard and transfer there to the ocean carrier) to be attractive. The experiment was a failure.

Carefully made estimates show, however, that by using the large type of lake carrier to Montreal and transferring there to an ocean carrier the costs of transportation to Atlantic Coast cities or to Europe, plus those of the transfer at Montreal, are considerably less than by the present routes.

The building up of new trade routes requires time. It is improbable to-day that any one of the lake cities is prepared to supply or to absorb the cargo of an economical European carrier in package freight, with the short interval between successive trips necessary in such a trade. The cargo volume is too great. Later, should such a trade route prove to be advantageous, the traffic might grow to truly great proportions. The combined traffic of several of the lake cities might reach a sufficient volume at once. The 4 000 to 6 000-ton lake carriers could serve one or more cities economically and the combined cargoes could supply the ocean carriers. In earlier days it was quite customary for outgoing cargoes to be collected in the warehouses of a port throughout a week or more, until enough tonnage was assembled to load a ship for the port of destination. This is no longer the custom. Ships sail from the great seaports at frequent intervals for all parts of the world. An interior manufacturer to-day ships his products just in time to reach the port before sailing day and avoids storage delays and charges. This fact is one of the causes of the decay of small ports and of the growth of great ports. The port warehouses of to-day are used mainly for imports awaiting sale.

With the lakes and their hinterland to provide and absorb cargoes, there is no reason why the well-equipped and well-managed Port of Montreal should not become an ideal transfer point.

It will be noted that the writer is not considering the transportation of bulk freight. Much grain moves now by water to Montreal, but the volume available for export from the United States grows less as the population increases. Part cargoes of grain would doubtless be carried from time to time to make up for

a deficiency of package freight. The traffic that would justify the deeper St. Lawrence Waterway must be of a character more similar to that of the Atlantic ports than to the bulk of the present lake traffic.

The cost of fitting the St. Lawrence River for lake boat navigation would not be excessive. It would be but little in excess of the value of the power produced. With such an improvement a thorough trial could be given to the project of direct water carriage between the lake ports and Europe and a new trade line built up. Later, if the increased expenditure for increased channel depths were shown to be justifiable, the deeper channel project could be carried out.

G. B. Pillsbury,* M. Am. Soc. C. E. (by letter).—This discussion relates to those parts of the author's paper dealing with the regulation of the Great Lakes; its purpose is to point out the engineering problems that must be solved before the economic feasibility of such regulation can be established, and before the plans for the necessary works can be drawn up, should regulation be found feasible.

Many members of the Society have regarded it as almost axiomatic that the regulation of the Great Lakes is inherently economically feasible; therefore, the writer may seem either bold or reactionary in asserting that the feasibility is yet to be proved. A consideration of the limitations that must be imposed on the levels of the lakes will, the writer believes, show that their regulation is not as simple and obvious a question as is sometimes assumed.

The interests concerned in the regulation of the Great Lakes are lake navigation, navigation of the St. Lawrence, power, and the owners of lands and improvements along the shores.

Obviously, lake navigation is interested in an increase in lake levels, that it may carry greater drafts through the channels connecting the lakes and into the harbors. Its greatest concern is the elimination of the extreme low levels, such as are now occurring. Within limits, present lake navigation is benefited by an increase in level at any stage of the lakes, as the short voyages and thorough organization of the traffic permit the utilization of the full draft available at the time. Lake navigation, however, would be adversely affected by any such increase in level as would hamper the operation of the loading or unloading wharves; for delays in loading and unloading are exactly as costly as delays and reduced cargoes en route. Navigation interests look also with extreme suspicion on any works in the connecting channels that would introduce delays to shipping, or that would tend to increase the hazards of navigation.

Navigation on the St. Lawrence is concerned with the minimum discharge from the Great Lakes System. The great Port of Montreal is not a tidal port, but a river port. There is about 20 ft. of fall in the St. Lawrence below Montreal, and the water level in Montreal Harbor depends on the volume of the discharge from the St. Lawrence and the Ottawa Rivers. The channel depths to and in Montreal Harbor have been won by the expenditure of millions of dollars in dredging, and are not lightly valued.

* Lt.-Col., Corps of Engrs., U. S. A.; U. S. Lake Survey, Detroit, Mich.

Power is obviously concerned, eventually, with increased minimum discharges. As long, however, as existing power installations use only a fraction of the minimum discharge of the river there can be no object in increasing this minimum discharge; nor will an increase benefit power until the development at some point on the river has reached a capacity corresponding to the minimum existing discharge. Considered from the economic viewpoint of the world at large, it will not be economical to expend large sums for regulation to increase the minimum flow for power purposes until all the developments on the river are beginning to reach the limit possible with the present minimum discharges.

The last interest concerned in the regulation of the lakes is the riparian owner, and this interest has sometimes been overlooked. At first glance it might seem that the increased lake levels proposed in any scheme of regulation that has been advanced are so small in amount, reaching a few feet only, that they could have no effect on the lands and the populous cities that border the lake. The investigation thus far conducted indicates, however, that the contrary is the case. Where land is valuable, improvements have been pushed beyond the absolute safe limit, as indicated by prior high water, to the reasonably safe limit, which would be surpassed by high water only at long intervals. There are many localities where a recurrence of past high waters would back up water in sewers, inundate the machinery pits of unloading wharves, and flood improved property in general. There is also the question of increased erosion of shore property at high lake levels.

The improvements effected have been made, in many cases, with full knowledge that they are subject to occasional damage by high water. It may be expected that the owners will insist that the frequency of such high waters will not be increased.

When the regulation of Lake Superior was under consideration by the International Joint Board, hearings were conducted to determine the fluctuations of the lake permissible under regulation. The so-called "high water of 1838" on Lake Superior is recorded at Elevation 605.32. From 1860 to 1914 the mean monthly level of the lake had been above 603.6 on four occasions, reaching in one month above 604. Nevertheless, riparian owners concerned, including municipalities and corporations owning wharf facilities, established at the hearings that any level above 603.6 would seriously injure their improvements, and the scheme of regulation prescribed by the Joint Board provides that the maximum regulated level of Lake Superior shall not exceed 603.6, except under such conditions of supply as would normally produce higher levels, in which case the levels should not exceed the level that occurred in the unregulated lake.

It may be confidently asserted that the riparian owners on any lake will impose a similar restriction on the regulated levels of the lake; that is, these will be limited to some level for normal operation which is lower than the actual highest levels of the past, with the provision that above this limit the lake must never rise oftener or higher than it would rise with the same supply, in Nature.

The writer has seen the view advanced that the riparian owners would have no legal claim for damages provided that the maximum levels heretofore reached were not surpassed as a result of regulation. He is not sufficiently versed in law to express an opinion whether damages would lie if the frequency of high waters were increased; but he is convinced that the Governments of the two countries concerned would never sanction wilful injury to a considerable number of their respective citizens.

As a consequence it is necessary to increase the low levels of the lakes for the benefit of navigation, without increasing the high levels, and to manipulate the reduced reservoir capacity remaining so as to improve the minimum outflow.

A brief consideration will show that this can be made possible only by increasing the discharge capacity of the outlets of the lakes to be regulated. With increased discharge capacity it will be possible to hold the lakes at higher minimum and mean levels, and, at the same time, to discharge an excess supply, whenever it may arrive, without raising the lake above the level to which it would have risen, in the state of Nature, with such supply. It is because the power canals at the St. Marys River provided an ample excess discharge capacity that regulation of Lake Superior, made necessary by the power works themselves, became feasible. A large increase in the discharge capacity of the St. Lawrence at the control section at the Galops is an inherent part of any future improvement of the International Section of the river for power and navigation, and, consequently, the regulation of Lake Ontario will naturally be combined with such an improvement.

It may be well to correct any misconception as to the operation of the regulating works at the outlet of Lake Superior. These works were, in their conception, for the purpose of diverting the water from the St. Marys River into the power canals. Since no such diversion works can automatically restore the natural regimen of discharge, they are of necessity operated under Governmental control. The operation is so directed as to decrease, in ordinary years, the fluctuations in the level of Lake Superior, while affording power users practically the entire river flow during dry years. These beneficial results are obtained, however, at the expense of increased fluctuations in the discharge from Lake Superior, made permissible by the existence of the enormous equalizing reservoir afforded by Lakes Huron and Michigan. The scheme of regulation, in the preparation of which the late Alfred Noble, Past-President, Am. Soc. C. E., had a prominent part, does not contemplate any hold-over storage from year to year. On the contrary, it provides for drawing down the lake each year in advance of the wet months in such manner that the inflow during those months can be safely handled.

The economic feasibility of the regulation of the lakes in general hinges, therefore, on the following questions:

(1) To what levels may the respective lakes be normally held without substantial damage to riparian interests?

(2) With an economically feasible outlet enlargement, what degree of improvement of lake levels and of discharge can be realized by regulation?

(3) Will the improvements realized be worth the cost of the outlet enlargement and of the works necessary to control the flow?

(4) What type of works, if any, acceptable to navigation interests, can be placed in the St. Clair River to control the outflow from Lake Huron?

The first question can be answered only by a thorough canvass of the situation at the principal harbors and towns along the several lakes.

Question (2) involves a computation of the cost of varying amounts of channel enlargement, with consequent increases of flow. It does not require much investigation to show that for an outlet such as the St. Clair River the cost mounts quickly with the increased discharge and soon becomes clearly prohibitive. The discharge through the St. Clair River during the winter months will certainly be less than the summer discharge, whatever the enlargement proposed; and it appears certain that the discharge capacity of the St. Lawrence during the winter months will also be limited, whatever the form and extent of the improvement. In any event no scheme of regulation can be considered that would increase the flow down the St. Lawrence at the time of the spring break-up, when, at Montreal and below, the river is packed with gorged and shoving ice.

With the limitations established, it then becomes possible to formulate rules for regulation, to test them by applying the supply factors of the several lakes established by past records, and to ascertain what improvement in present condition, both as to levels and as to discharge, can be realized.

In preparing and testing a suggested method for regulation the temptation is strong to assume that it will be possible to predict, in advance, the probable supply. Any scheme of regulation is necessarily based on prediction, which limits itself, however, to the assumption that the future will be no worse than the past, so far as maximum and minimum supply is concerned. To predict the future supply to a lake from the present rainfall records is a different, and the writer believes, an impossible task. The net water supply to the lake is the inflow into the lake, plus rainfall on the lake, less evaporation from the lake surface. Whatever hopes may be had that the inflow into a lake from its drainage basin may be predicted in advance from the rainfall records on its water-shed, no advance prediction can be hoped for regarding the variations in the rainfall on the lake and the evaporation from its surface. The latter two add to or diminish the supply as soon as they occur. Thus, the rains of August will have some effect on the inflow during September, but the temperature and humidity records of August will have no effect on evaporation during September. If it is realized that the average loss to Lakes Huron and Michigan from evaporation exceeds the inflow of the St. Marys River, it will be easy to see how uncertain any prediction of supply must be.

In estimating the benefits to navigation resulting from a proposed regulation (Question (3)), the cost of regulating works must be compared with the cost of securing a like measure of improvement by dredging. The author has shown the very large benefits that can be secured to navigation by deeper channels. It is quite immaterial, however, so far as navigation is concerned, whether depth is secured by dredging or by raising the stage. On the other

hand, a free, open and unobstructed channel through the St. Clair River is an unquestionable asset to navigation, the value of which must be debited against any regulation scheme in proportion to the obstruction or constriction imposed by the works in the St. Clair proposed in that scheme.

In summary, the writer hopes he has shown that the economic feasibility of regulating the Great Lakes is not axiomatic, but that it can be established only after due and full investigation. The instructions to the present Joint Board of Engineers on the St. Lawrence Waterway require such an investigation, which is in course, and which should form a basis for a determination of this vital question.

About fifteen years ago a board of eminent engineers answered the question in the negative. Whether or not present conditions and new facts warrant a reversal of this prior finding is a matter that can well be given the best engineering thought of the Society.

L. F. Harza,* M. Am. Soc. C. E.—It has been said by Guy E. Tripp, Chairman of the Board of Directors of the Westinghouse Company, that the general prosperity of any country or section of any country is directly proportional to the amount of mechanical power in use by that country. It is mechanical power only that makes the difference between the present and the time when a man worked 12 or 15 hours a day to make a living for his family, and when his wife spun the yarn and made the clothes, and the children worked from early childhood; it is only mechanical power that makes the difference between the standard of living and the average wage then and now. If that is the case—and it has been very well demonstrated—and if the eastern section of the United States is to receive all the benefit of this power development, why not let the Middle West have the benefit of the transportation development if there is any benefit to be derived.

Elliott J. Dent,† M. Am. Soc. C. E. (by letter).—Attention has been called by Mr. Gardner S. Williams to the fact that the navigation channels through certain reaches have been deepened, and he states that:

"Students of hydraulics can readily decide whether the deepening of channels that were between 8 and 12 ft. to 21 ft. in depth, has or has not enabled more water to flow out of the upper into the lower lakes."

The paragraph in which this statement occurs applies more accurately to the channels through the Lower Detroit River than to any others. The writer is now in charge of this improvement and desires to lay a few additional facts before the members of the Society.

The aggregate width of all the natural channels through a section selected as more or less typical of the reach in question was approximately 11 000 ft. The improved channels are two in number, one being 600 ft. wide and the other 450 ft. wide, making the combined width of the deepened channels 1 050 ft., or about one-tenth the natural width. Part of the rock excavated from the improved channels has been carefully distributed in such a manner as to obstruct portions of the natural channels with a view to neutralizing

* Cons. Hydro-Elec. and Hydr. Engr., Chicago, Ill.

† Lt.-Col., Corps of Engrs., U. S. A., Detroit, Mich.

the effect of the deepening. The question whether complete compensation has been effected is one that is still under consideration and measurements are made annually to supply the data for studying the subject.

The data thus far accumulated fail to demonstrate conclusively any change in level at the Fort Wayne gauge about 10.5 miles above the head of the deepened channels. Any effect that may eventually be found at Fort Wayne will necessarily be considerably reduced before the lower end of Lake Huron is reached, as the intervening length of river channels is about 38.75 miles.

KENNETH L. DE BLOIS,* JUN. AM. SOC. C. E. (by letter).—There are several fundamental principles that should be considered before embarking on the improvement of any inland waterway.

Experience has proven that ocean steamships will go as far inland toward the center of production and industry as physical conditions will permit. As examples of ports developed at the head of ocean navigation may be cited: Philadelphia, Pa., 101 miles up the Delaware River; Baltimore, Md., 190 miles up the Chesapeake Bay; New Orleans, La., 100 miles up the Mississippi; Baton Rouge, La., 190 miles up the Mississippi; Portland, Ore., 113 miles up the Willamette River; and Montreal, Que., Canada, 1 000 miles up the St. Lawrence River.

Recognition of this fact in the past would have prevented uneconomical expenditures on such ports as Halifax, Nova Scotia, and Montauk Point, Long Island. The St. Lawrence Waterway fulfills this condition in that it will permit ocean steamships to go into a territory rich in industry and agriculture. The fact that such steamships already come to Montreal, navigating a tortuous channel for many miles in preference to making Halifax or St. John, N. B., Canada, their western terminal, supports this claim.

Transfer charges are a very important consideration and a waterway to be economically feasible must cut the number of transfers to a minimum. The New York State Barge Canal was built to insure the transfer of grain at Buffalo, and New York, N. Y., and not to eliminate them. Because of this the grain trade has practically disappeared from the canal. The St. Lawrence Waterway will eliminate most of the existing transfer charges by permitting boats to be loaded at the head of the lakes and proceeding to their destination without further transfer.

As a substitute for the St. Lawrence Waterway a deep canal across New York State has been suggested. Even if the immense sum of money were at hand to build a canal it is extremely doubtful whether ship-owners would risk their vessels navigating a narrow channel for several hundred miles across the State. This project should not be seriously considered as a substitute. The proposed St. Lawrence Waterway must not be confused with a narrow ship canal. The author clearly outlines the use of dams and pools to give a wide channel for a greater part of the distance.

It has always puzzled the writer to understand why a certain group who are so adverse to the Great Lakes-St. Lawrence Waterway, where a large freight

* Cincinnati, Ohio.

traffic already exists, at the same time advocate the expenditures of huge sums of money on barge canals where little or no traffic exists and where there is no prospect of any. On the editorial page of nearly every Middle Western newspaper will be found a platform advocating a barge canal as the one means of creating a permanent prosperity for their community. It is not the writer's intention to discuss these various projects but merely to emphasize that money should be spent on waterways which will be used when completed. The Great Lakes-St. Lawrence Waterway with ocean traffic at Montreal and the large existing traffic on the lakes can leave no doubt but that the proposed waterway will be used.

C. S. Riché,* M. Am. Soc. C. E. (by letter).—Although the opening of the Great Lakes to ocean traffic seems inevitable, it has nevertheless been under discussion for a long time, and there seems to be enough opposition in certain quarters to keep it "under discussion" for many years longer.

The situation is somewhat similar to that which existed 35 or 40 years ago, with respect to the Gulf of Mexico. For many years there was opposition to the creation of deep-water ports in the western part of the Gulf. The Southwest had then only recently been linked to other parts of the country by rail. Long rail hauls to Eastern ports were desired by many interests. Nevertheless the improvement of Galveston Harbor was actively undertaken in the early Nineties and was followed by the improvement of adjacent harbors at Sabine Pass, Port Arthur, Beaumont, Orange, Bolivar, Texas City, and Houston, Tex.

All these places are relatively near together. Their access to the ocean is either by Galveston Entrance or by Sabine Pass. They form the nearest ocean outlets for approximately one-fifth the area of Continental United States. Their commerce in and out, foreign and domestic, was very small before these harbors were deepened, and was subjected to lightering and other transfer charges which none but the most valuable freight could bear.

A record of this commerce has been kept by the U. S. Engineer Department, and appears in the Annual Report of the Chief of Engineers for 1924, the record for 1923 being the last one given.

Beginning in 1893, a few years before the first harbor was deepened, and listing the annual totals at intervals of five years discloses that the freight passing in and out of Galveston Entrance and Sabine Pass was as follows:

Year.	Short tons.
1893	415 403
1898	3 168 464
1903	4 867 965
1908	(Record incomplete)
1909	5 825 608
1913	9 915 829
1918	11 090 405
1923	24 622 522

* Col., U. S. A. (*Retired*), St. Louis, Mo. Colonel Riché died on March 20, 1926.

The general development of the Southwest has had much to do with this great increase, but *vice versa* this development has chiefly resulted from the improvement of these harbors. There is no indication that the commerce of the Port of New York and other Eastern ports has suffered from this development but rather has profited and increased by reason of it.

The Great Lakes penetrate into the continent nearly as far to the westward as the Gulf of Mexico, into a section of greater natural resources than the Southwest. Although the North and Middle West have already been extensively developed, a much greater progress is possible and their accessibility to ocean traffic would stimulate this further development.

New commerce, increasing as has that of Galveston and Sabine Pass, could be expected at the Western Lake ports of Port Arthur, Ont., Canada; Duluth, Minn., and Chicago, Ill. Adjacent territory would develop more intensively, and Montreal, New York, and other Eastern ports, together with Canada and the United States as a whole would be benefited and not injured as a result.

Opposition to this improvement because of the fear of injuring existing business is ill-advised. Any development that would directly benefit so large a territory could not fail to benefit the continent as a whole. One such benefit not often mentioned would be the ability to build sea-going ships at lake shipyards. This can be done to-day but, with the exception of vessels of the small St. Lawrence Canal size, these lake-built boats have to be towed to the seacoast in sections and there assembled. Consequently, little such work is now done on the Great Lakes.

Steel is manufactured at a number of points on the lakes and there is an advantage in having shipyards close to the steel mills. With easy egress from the lakes for the product of the shipyards, it would be surprising if such an industry did not soon become extensive.

There would also be a benefit, as Mr. Shenehon points out, if lake vessels could be available for ocean service during the winter instead of lying idle for five months each year. The additional revenue thus obtainable might easily pay for such strengthening as would adapt these vessels to ocean service. At times, there are demands for additional carriers on the ocean, which would make such service quite profitable.

It is unnecessary to go back further than the dark days of the World War, when the submarine menace was at its height, to recall the demand for vessels for ocean service. Old boats, many far less seaworthy than the average lake vessel, were pressed into service and helped to save the day. Meanwhile, for five months each year, the great fleet of lake vessels lay idle, incapable of getting to the ocean. Had it been possible to transfer this fleet or any large part of it to the sea at that time it seems probable that the resulting saving would have paid the cost of improving the St. Lawrence River and the Great Lakes several times over.

It is to be hoped that these conditions will not recur, but they may, and it would seem advisable next time to be ready for them. Where that readiness will also result in a large commercial benefit, it would seem wise not to

keep the subject "under discussion" indefinitely, but to take early steps to bring about results.

E. G. WALKER,* M. AM. SOC. C. E. (by letter).—The writer has read this paper with interest, for there are few individual engineering proposals in the limelight at present which have so general an interest, or which, if carried out, would have such far-reaching consequences. To appraise fully the magnitude and nature of the proposals for regulating the Great Lakes and the St. Lawrence River requires complete inspection and first-hand acquaintance with all the sites referred to by the author. The writer is at a disadvantage in this discussion in not possessing such acquaintance; hence, he prefers to confine his statements to more general matters.

Critics of plans for the greater utilization of the St. Lawrence question not so much the possibility of carrying out the works as the likelihood of their full use when completed. Criticism of details is seldom or never heard. No doubt this is due in part to the fact that none of the works proposed is of a startling nature or exceeds in general form and scope the very fine results which have already been achieved both in regard to power development and as to the provision of navigation facilities. At the same time the construction problems involved are not simple. The condition which makes the St. Lawrence unique as a power-producing river is the enormous magnitude of the reservoirs out of which it flows. While this gives it a minimum fluctuation of flow, it also means that there are no slack-water periods, such as occur on most rivers, of which advantage can be taken to carry out under-water works, and the whole flood volume has to be provided for in any plan for controlling the water during construction. It is not suggested that these and similar difficulties cannot be overcome. The writer merely raises the point because it is one which is apt to be overlooked. On the other hand he considers that a very great reason why the whole proposition should be given the fullest and most rational consideration is because it is one that does not involve any new or startling departure, but only requires the construction of works similar in character to those which have been carried out already in various parts of the world. The total expenditure proposed is vast and obviously cannot be undertaken without a very full study by men of high qualifications; but should the work be decided on, each unit into which it is divided is a solvable engineering problem. Although, at present, the total cost is merely a guess, it is certain that the proposals can be carried out in detail, even if some of them may prove to be difficult.

The main object of the paper being to advocate the construction of a deep-water navigation from the head of Lake Superior to the sea, it is disappointing to find inadequate consideration paid to the primary features of such a waterway. The paper leaves an impression that the premises on which any plan for a waterway must be built have been considered far too lightly. The idea of being able to take a large ocean-going ship into the heart of a continent is one which inevitably must make a strong appeal even to the dullest imagination, and the glamor of the idea is apt to spread in an unwarranted manner

* London, England.

and to mask opposing features which otherwise would stand out in a clearer light. Enthusiasm for the greatness of the development and for its possible widespread influence seems in the present instance to have drawn attention away from material facts which are of much too great importance to be passed over lightly.

As evidence of this the writer notes how little idea is given by the author of the type of ship which it is proposed to use on the waterway. He states:

"It will be assumed that engineers will solve the problem of composite vessels to traverse the fresh-water seas and the salt seas; that the evolution of this vessel will come in the ten years between the definite decision to construct the waterway and its completion; and if not in this decade then in some of the early decades of the century."

Instead of making the assumption that it would be possible to find a type which can be used on the waterway when built, why not give some consideration to the matter now? If the search for a type of ship suitable to the special conditions of the case and for methods of handling such ships and their cargoes is successful, then it is at least known that if the waterway is provided it can be used.

From the discussions on this point the writer concludes that the familiarity of the people near the Great Lakes with the craft they use has distorted the first of these problems into one of needless complexity. The Great Lakes freighter is a unique type of vessel which has been evolved to suit the special conditions obtaining there. It differs from the ocean-going steamer as much as a street car differs from a railroad coach and for a similar reason. The lakes freighter is free from many of the conditions imposed by ocean service. The result is that it has been possible to evolve a vessel of comparatively light dead weight and of high efficiency both in regard to stowage of cargo and to handling it. With such ships the local traffic of the Great Lakes is transported in the highly economical manner that has justified the installation of expensive special machinery for loading and discharging. It is agreed, and rightly, that these ships are not suitable for general ocean travel, but by some inexplicable inversion of reasoning, it is then assumed that the opposite proposition is also true, namely, that ocean steamers would not be suitable vessels for going up the St. Lawrence Waterway to ports of the Great Lakes.

To any engineer who has been concerned with ships or with the provision of harbor facilities for sea-borne commerce, this idea must appear untenable. Admittedly the ocean-going ship could not compare with the lakes freighter for interlake services. It would not be used for such work; it would deal with cargoes which the lakes ships could not handle; but both types of vessel use similar prime movers, propel themselves by screws of similar kind, and are steered and maneuvered similarly. The ship which can cross the high seas can equally well traverse the Great Lakes and negotiate any connecting waterways, provided the dimensions of these are suitable. One is at a loss, therefore, to understand whence arises this fetish of the hybrid ship. If cargo is to be consigned overseas it must be sent in an ocean-going ship; if inland produce is not to be sent directly overseas there is no reason for constructing a deep-water navigation to the farthest possible point inland.

The only excuse for attempting to bring the hybrid into being is that it would aim at combining the sea-going qualities of the one type with the efficiency of stowage and ease of loading of the other. Such an aim is largely a myth. The basis of design of all cargo ships is a complex compromise between a number of factors, often mutually antagonistic, such as seaworthiness, speed, ease of handling, cargo capacity, kinds of cargo to be transported, radius of action, etc. and in arranging the details account has to be taken of extreme conditions. In the case of ocean-going ships designed for the projected St. Lawrence navigation such conditions are provided by the high seas in practically every detail, except over-all dimensions, even to the relatively minor condenser problem referred to in the discussion. The principal possible complicating condition which a waterway would cause would be tonnage measurement rules. These, of course, might materially influence the design of the ships, but can hardly be discussed at the present stage. There is no reason to anticipate that if the proposed waterway should be constructed it would be found necessary to introduce freak tonnage regulations. The inevitable conclusion, therefore, is that if the St. Lawrence Waterway should be opened as a work of the magnitude contemplated by the author, it will be used, as have all waterways of a similar kind thus far constructed, by the normal type of ocean steamers which would voyage between overseas ports and the various ports along the waterway.

Whether the present terminal facilities in the Great Lakes ports are suitable for the contemplated traffic is a matter which has not been mentioned in the paper. The ocean steamer differs considerably from the lakes vessel in the arrangement and dimensions of hatchways and the facilities available for stowing and discharging cargo, and must continue so to differ because of the provisions which have to be made to meet open sea conditions. Furthermore, the opening of the Great Lakes ports to overseas commerce would probably have the effect of causing a large increase in the amount of general cargoes passing through these ports in comparison with the special cargoes which are now the principal ones handled. Advocates of the proposed waterway do not seem to have considered adequately that one of the main effects of a deep-water direct connection to the sea might be expected to be the opening of numerous new inland ports to the exportation and importation of sea-borne goods, and that if this movement were successful, it would alter very greatly the average character of the shipping using the Great Lakes ports. This would mean that terminal and port facilities suited to overseas traffic would have to be provided at lake-side ports, and in many cases might entail considerable expenditure for re-arrangement of wharves, warehouses, transit sheds, cranes, sidings, etc., and for the provision of new works, in order to handle products which at present are not carried by water at all as far as the territory of the Great Lakes is concerned.

Assuming the proposed waterway to be constructed and provision made for accommodating any type of ship, it is unlikely that vessels would enter and incur the expenses of lockage and other dues (which, in view of the great total lift of 500 to 600 ft., must be heavy) unless they were on definite charters.

Statements that have been made as to the possibility of tramp steamers in search of cargo visiting Great Lakes ports in the same way as at ocean ports are far-fetched and unlikely. The costs of operating such a navigation as that outlined in the paper must be fairly high. They must be sufficient to increase very materially the cost of transport over the 1 340 miles above Montreal.

The author has taken for the purposes of this paper a depth of 25 ft. with provision for a future increase to 30 ft. and in so doing has used correspondingly moderate dimensions for the lengths and breadths of locks and other permanent works. Apparently, his basis is a lakes freighter 600 ft. long, with a 60-ft. beam, 24-ft. depth, and a cargo capacity of 10 000 tons, although as already pointed out it is unlikely that such a vessel would be used for overseas commerce. It is probable that provision for 10 000-ton ships would be more than sufficient to meet the requirements for a long time. Of the world's ships 50% do not exceed 1 000 tons and although there is a tendency to increase the size of vessels of between 5 000 and 10 000 tons it is unlikely there will be, at any rate for as long a period as the present generation need consider, more than a small minority which could not use a waterway large enough to accommodate a 10 000-ton, ocean-going ship. To make certain of this, however, it might be well to give increase of breadth to all permanent works, since the vessel selected by the author for his standard is narrow in proportion to its length. A 10 000-ton intermediate ship would normally have a beam of about 60 to 70 ft. and be appreciably shorter than the lakes steamer. The dimensions proposed for locks, namely, 800 by 80 by 30 ft., should be ample.

In discussions on the power development aspect of the St. Lawrence Waterway, objection to the plans has been taken on the score that so large an output could not be used. Accepting the estimate given in the paper, the author appears to conclude that an ultimate total of nearly 7 000 000 h.p. is available, made up as follows:

Present development:

	Horse-power.
Canadian	700 000
American	570 000
Total	1 270 000
Possible additional power (with regulation)	4 424 000
Possible improvements at Niagara	1 160 000
Total	6 854 000

The writer has no figures at hand relating to American power developments, but taking the current figures for the Canadian Provinces of Ontario and Quebec only, the following water power is already in use:*

	Horse-power.
Ontario	1 445 000
Quebec	1 116 000
Total	2 561 000

* Annual Report, Dominion Water Power and Reclamation Service, 1923–24.

This power serves a population of about 5 500 000 and includes the 700 000 h.p. given in the author's figures. It is equivalent to about 0.47 h.p. per person. On this basis there would remain 6 154 000 h.p. to be utilized, requiring a population of more than 13 000 000. The power requirement in the Provinces of Ontario and Quebec is greater than the average for the United States and Canada, which works out as 0.44 and 0.35 h.p. per head, respectively. It is probably greater than the average for the whole territory tributary to the Great Lakes and the St. Lawrence. Hence the development of the two countries would have to be greater even than is implied by the indication of this simple statistical calculation. Bearing in mind that this population figure is of the magnitude of the total increase of the population of the United States in the last ten years, one gets some impression of the size of the problem involved in harnessing the whole of the St. Lawrence power.

There are two potential competitors with the present plan that have to be reckoned with, namely, (1) other hydro-electric power; and (2) power from coal. Roughly speaking, these resolve themselves into Canadian and American competition, respectively. The large undeveloped sources of power in Canada and particularly in the Province of Quebec are well known and the 5 000 years' supply of bituminous coal in the United States to which the author refers may well be formidable competitors. Remarkable advances have been made in recent years in the economical use of coal as a source of power and it is noteworthy that some of the most economical power stations in the world are situated in the area treated in the paper. The writer does not agree, therefore, with the reasoning that because supplies of coal are ample, no concern need be felt about saving coal. No hydro-electric power plan can oust steam power unless it can make an appreciable reduction in the cost of supply of current. The fact that such large deposits of coal are available seems to the writer to make the use of that material as a source of power a big factor in considering the development of the huge hydro-electric propositions within a relatively short distance of the largest coal districts of the country. One would like to have much closer estimates of costs of power than are given in the paper, and also to have for comparison figures as to costs of generating from coal, before venturing on definite opinions.

In the Province of Quebec the power supply situation is different, but none the less subject to conditions which must be very carefully considered in connection with this St. Lawrence project. The Province of Quebec is only at the beginning of its development, and it is hardly possible to forecast exactly along what lines such development will take place; but the northern parts, which are yet almost unexplored, contain much mineral wealth that must inevitably be developed in the course of time and there are large timber and agricultural resources likewise awaiting development. Further, the Province contains sources of hydro-electric energy that are certainly much more than sufficient for its present needs, and that may well afford all the power required for mining and other developments for a long time to come. In the majority of cases the potential industrial developments are placed nearer the undeveloped power resources of Northern Quebec than to the sites referred to in the paper. It is certainly more likely that the power required for opening up what must

develop some day into one of the most important metalliferous areas on the whole Continent will be supplied from the sources near at hand before having recourse to the more remote potential supply from the upper reaches of the St. Lawrence.

Most engineers will regret that the utilization of this wonderful water system cannot be treated as a purely economic and technical problem. It is unfortunate that politics, international as well as national, are so dominantly involved, for the considerations thus brought into the subject are not those best calculated to advance the interest of humanity. Be that as it may, however, the situation remains. The writer is not concerned here with political matters except so far as their influence on the large engineering proposition is concerned. From his examination he has reached a few simple conclusions:

1.—As the greater part of the channel (including most of the proposed power development) of the St. Lawrence is entirely within the Province of Quebec, the attitude of that Province must be inevitably a dominating factor in the scheme.

2.—Quebec opinion generally is that the Quebec Port of Montreal would lose much of its trade if shipping were free to pass on up to the head of the Great Lakes.

3.—The people of Quebec realize the potentialities of their Province and also the overwhelming importance, living as they do in a cold country with no coal deposits, of controlling fully all the sources of power they have, and they are not likely to agree to any proposal for generating power for export.

4.—With the passing of time the industrial activities of Quebec will extend more and more toward the north and northeast, that is, in general, down the St. Lawrence away from the part of the river available for power generation.

That the opening of a waterway for large ships up to Lake Superior would injure the Port of Montreal, the writer does not believe. To extend navigation above Montreal would doubtless divert a certain amount of traffic from that port to points above it; but, on the other hand, the waterway may quite well be expected to compensate by creating traffic not now existing and to bring into being new lines of commerce, from which Montreal will benefit in common with all the other ports along the waterway.

On the question of power development, however, the writer does not believe that at present progress will be served best by the St. Lawrence plan. Doubtless it will come, for ultimately the world will not be able to afford to let any possible source of energy run to waste; but before this time, much more development will have occurred in the northern parts of the St. Lawrence Basin, and the sources of power in these areas may well be utilized before economic necessity brings about the harnessing of the St. Lawrence. Development is gradually pushing seaward along the north bank of that river, and power plants exist on a number of its northern tributaries. The writer believes that there is greater probability that this development will continue than that the St. Lawrence power plan as outlined in the paper will be undertaken in the near future.

He does not lose sight of the fact that on the south side of the St. Lawrence, in a direction east from Montreal, there is an area of constantly increasing industrial development. Here, however, the proximity of Montreal on the one hand and of industrial areas over the American border on the other has been the cause of growth rather than the exploitation of natural resources that must ultimately direct the trend of progress in Northern Quebec. If, as seems likely, export of power is prohibited by the Government of Quebec, it is open to question whether the territory south of the St. Lawrence will be able, for many years to come, to utilize more than a small fraction of the power developed under the author's proposals.

Regulation of the Great Lakes in the interests of lake navigation is obviously a matter that stands on quite a different footing. There is everything to be said in favor of proposals that seek to maintain the water levels of the various lakes to relatively constant heights; but this is a matter that can be considered apart from the waterway proposal or the development of power on the St. Lawrence.

Francis C. Shenehon,* M. Am. Soc. C. E. (by letter).—The writer is grateful for the discussions, which supplement and illuminate his paper. These are mostly fair-minded and helpful in evaluating the several elements entering into this great project.

Let it be set down that the writer is not promoting this Waterway to the Sea. Instead, he states its ultimate economic desirability and therefore its inevitability. And he does not fix an early date of completion, because too many political and regional elements arrest the free play of economic forces; but he does anticipate immediate action on the restoration, deepening, and maintenance of the right of way of the Great Lakes. And he does advocate immediate action on the International portion of the Rapids Section of the St. Lawrence River, extending from above the Galops Rapids to the head of Lake St. Francis, primarily as a water-power project, but so developed that the ultimate deep-draft waterway will be provided for adequately.

When 25-ft. drafts become available in the Great Lakes System, in the Welland Canal, and through the International St. Lawrence River, the remaining developments, between Lake St. Francis and Lake St. Louis and through the Lachine Rapids to Montreal, will follow in due course, possibly depending on the time when additional electric energy is needed in Canada.

It appears unnecessary to answer any discussions bearing on the commercial feasibility of the navigable waterway. The paper itself is clear and explicit as to the writer's views, which are still unchanged. The blending of navigation and water power on the St. Lawrence River is obvious. To what extent the opulence of the energy element will subsidize the transportation element is a matter of opinion. The utilization of all the water power as a commercial enterprise is certain; the utilization of the navigable waterway to the limit of its capacity is still uncertain. The water which will create untold millions of kilowatt-hours and horse-power-years, comes in largest part from Lakes Superior and Michigan-Huron and represents the contributions

* Cons. Engr., Minneapolis, Minn.

of the States of Minnesota, Wisconsin, and Michigan, and the middle and western portions of the Province of Ontario. The writer proposes to utilize, in the interest of larger continuous flow in the Niagara and St. Lawrence Rivers, the storage capacity of these great reservoirs. Navigation interests do not view favorably any draw-down in these reservoirs for the benefit of water power; and water-power interests do not view favorably any subsidization of navigation.

It is significant that navigation is the vital economic element for the United States rather than water power; and that for Canada, water power is the vital economic element rather than navigation. More than 90% of the commerce of the Great Lakes is American. With equal division of water at Niagara Falls and on the International Section of the St. Lawrence, approximately 67% of the ultimate water power will be Canadian.

Notwithstanding lesser commerce and lesser population, the Canadians are showing high optimism and enterprise in extending deep drafts down to Lake Ontario and into the Upper St. Lawrence by the expenditure of more than $100 000 000 in the New Welland Canal. On the other hand the United States—with a lake commerce eight times greater, with a population in the States bordering the Great Lakes more than four times greater and in the country as a whole more than ten times greater—has had neither the optimism nor the enterprise for a quarter of a century to secure and maintain even reasonably good drafts in this vital internal waterway; and has added no link—aside from the Davis and Sabin Locks at the "Soo"—to the ultimate waterway to the sea. And the Canadians have outstripped the United States in the volume of developed water power in the Niagara and St. Lawrence Rivers.

In reply to the suggestions of Mr. Hogg, reference is invited to the judicial Engineering Reports (1925) of the Board of Review of the Sanitary District of Chicago. This Board was the most eminent group of engineers ever called together to investigate a great sanitary and hydraulic problem. It is well to point out the significant fact that the diversion of 50 000 cu. ft. per sec. in St. Marys River has yielded some beneficial horse-power years; and after the obvious engineering device of regulating works became effective, has made Lake Superior better for navigation. The local conservation use of the water is therefore twofold; and, in addition, the reservoir value of Lake Superior will eventually help to stabilize the energy output of the St. Lawrence River and the navigational use of the St. Lawrence Waterway. In any use of the water of the Great Lakes true economic analysis must balance the value of working water against wasting water; or must compare the present worth of water serving several purposes with the present worth of water to serve dual purposes twenty or thirty years hence. Engineers may leave certain legal questions to lawyers and statesmen and evaluate the service of the water, after regulating works have restored losses of depth and created storage to conserve in the future the wastes characterizing the past and the present.

Perhaps the writer's proposal to stabilize the flow of the St. Lawrence River by utilizing the reservoir capacity of Lakes Superior, Michigan and Huron, with some sacrifice of navigable depths in these lakes, represents

more cosmopolitanism than patriotism. In analyzing a physical problem it is not easy for the engineering mind to give due weight to such intangibles as political boundaries and regional psychology. It may be well, however, to retain a detached world citizenship, leaving to statesmen and diplomats the allocation of the economic benefits possible with the best physical solution. Perhaps optimism and enterprise should be accorded the little sacrifice suggested.

The writer's thesis might be entitled "Conserving the Water Wealth of the Great Lakes System"; because in the paper itself and in the discussions evoked the value of the water and the ways of storing and utilizing it are developed. The water is valuable for navigation within the lakes—to the Gulf of St. Lawrence and to the Gulf of Mexico—and for water power in the Niagara, St. Lawrence and Illinois Rivers.

Hydrological events, the views of discussing engineers, and months of further study have modified in some respects the tentative conclusions of 1924. The chief hydrological event is the unprecedented prolongation and accentuation of the period of meager supply in the Great Lakes System, beginning in 1921 and still (March, 1926) prevailing. The mean supply for 35 years—1891 to 1925, inclusive—is 231 500 cu. ft. per sec. The supply and the St. Lawrence River outflow for the past 5 years are:

Year.	Mean supply, in cubic feet per second.	Mean outflow, in cubic feet per second.
1921	198 000	229 000
1922	215 000	229 000
1923	204 000	214 000
1924	197 000	221 000
1925	168 000	209 000
Mean	195 200	220 400

Assuming that the levels of all the lakes were maintained without any accumulated lowering and that 9 000 cu. ft. per sec. were diverted into the Illinois River, the mean outflow in the St. Lawrence River would have been 186 200 cu. ft. per sec. Conversely, assuming that the St Lawrence flow had been maintained uniform with a volume of 220 000 cu. ft. per sec., the levels of all the lakes would have been lowered 2.0 ft. to supplement by storage the deficient supply; and in order to recover the 2.0 ft. of surface-level loss in these 5 meager years, it will be necessary—with fixed St. Lawrence River outflow—to have 5 years of opulent supply as much in excess of normal as the meager years are below normal. Such a compensation in hydrological fortunes is vastly improbable.

It is interesting to note the actual maximum and open-season minimum monthly outflow volumes of the St. Lawrence River in this period of comparative water famine as given in Table 7. The largest unregulated outflow comes in months when the Harbor of Montreal is deep because of the large Ottawa River discharge; and the smallest outflow comes in the fall months when navigation needs ample river volume.

In these fairly generous outflow volumes for the St. Lawrence River is an excellent illustration of the antithesis of uniformity of reservoir levels and uniformity of outflow volumes. In 1925 the supply is only 73% of normal, but the outflow is more than 90% of normal. The reservoirs of the lakes automatically waste the waters of the lakes to the ocean. The utilization of regulated Lake Ontario alone for storage, with the natural automatic drop in the big upper reservoirs, would have sufficed to maintain a reasonably uniform outflow in the St. Lawrence River. In the years 1926 and 1927, however, the St. Lawrence outflow must be meager, unless extraordinary water abundance prevails; because the St. Clair River with the present low Michigan-Huron elevation cannot outflow its normal supply. This must cause a deficit equal to the volumes to be stored in Lakes Michigan-Huron. This deficit in the St. Clair River contribution to the St. Lawrence flow will lessen each year until Lakes Michigan-Huron reach some elevation such as 580.2 ft. in the beginning of the year 1936. The elevations of the various lakes are as given in Table 8.

TABLE 7.—Maximum and Minimum Open-Season Discharges of the St. Lawrence River.

Year.	Month.	Outflow, in cubic feet per second.	Month.	Outflow, in cubic feet per second.
1921	May	253 000	November	213 000
1922	June	258 000	December	210 000
1923	July	237 000	November	203 000
1924	June	244 000	December	208 000
1925	May	230 000	October	202 000

The problem of the co-ordinated regulation of the Great Lakes is the adjustment between the maintenance of the best surface elevations and the largest practicable minimum outflow in the St. Lawrence River. The degree of uniformity in the Niagara River is of relatively lesser importance, because water power may use a fixed volume of, perhaps, 100 000 cu. ft. per sec., while the volume applied to the preservation of the scenic grandeur of the Falls may be diminished in times of restricted flow.

TABLE 8.—Elevations of the Great Lakes.

Lakes.	Elevations, in Feet.		Deficiency, in feet.
	January 1, 1926.	Desirable.	
Superior	600.2	602.5	2.3
Michigan-Huron	577.5	582.0	4.5
Erie	570.2	573.0	2.8
Ontario	244.4	247.0	2.6

If the volume of prime flow in the St. Lawrence had been limited to 220 000 cu. ft. per sec. instead of the 230 000 cu. ft. per sec. computed in Table 2, the elevations of the Great Lakes on January 1, 1926, would have been as follows:

Superior, 601.0 ft.; Michigan-Huron, 580.5 ft.; Erie, 571.5 ft.; and Ontario, 245.5 ft. The present unregulated deficiency, spread uniformly over all the lakes, would be 3.4 ft. Under co-ordinated regulation with a minimum flow in the St. Lawrence of 220 000 cu. ft. per sec., the deficiency would have been only 1.5 ft. The difference of 1.9 ft. represents the gain in navigational depth possible with co-ordinated regulation. Its value in the year 1926 would be not less than $10 000 000.

It is illuminating, if hazardous, to forecast the regain of surface elevations in Lakes Michigan-Huron based on average supply conditions and unregulated outflow in the St. Clair River. In making this forecast (Table 9) it is assumed that the restoration of regulated Lake Superior will be secured at the rate of about 2 in. per year—representing storage at the rate of 5 000 cu. ft. per sec.

TABLE 9.—Assumed Return of Lake Elevations.

Year.	Elevations, in Feet, January 1.		St. Clair River.	
	Superior.	Michigan-Huron.	Outflow, in cubic feet per second.	Quantity below normal, in cubic feet per second
1926	600.2	577.5	140 000	45 000
1927	600.4	578.5	156 000	29 000
1928	600.6	579.1	166 000	19 000
1929	600.7	579.5	172 000	13 000
1930	600.9	579.7	176 000	9 000
1931	601.1	579.8	.....	.....

Forecasting the unregulated outflow in the St. Lawrence River on the basis of normal or average supply, the mean volume of discharge for 1926 should be about 185 000 cu. ft. per sec., and for 1927 about the same quantity. It is an even chance that it will be somewhat greater and an even chance that it will be somewhat less. A portion of this outflow must come from the further draining and lowering of Lakes Erie and Ontario.

The serious deficiency in water supply of the past five years (1921-25) with resultant low lake levels and crippled transportation capacity demonstrates clearly the need of engineering control to conserve in years of abundant yield the waters of the Great Lakes and to expend by budgeted release in lean years the accumulated savings. The present concern over the depleted condition of the lakes had its parallel in the low-water period of 1895-96. The engineering remedy proposed then—more than a quarter of a century ago—was regulating works in the Niagara River.

Will regulation work? Colonel Pillsbury expresses doubts and Mr. Sabin after more than thirty-five years spent in Great Lakes problems—much the same as the writer's years of experience with these problems—is not sure. It is certain that the natural automatic operation of the lakes has failed to maintain the best navigable waterway.

Mr. Sabin refers to the years 1910 and 1911 as illustrating the complexity of regulation. As a matter of fact a detailed analysis of the hydrology of

these years—and of 1912 as well—demonstrates the practicability and necessity of regulation. In 1910 the supply naturally tributary to the St. Clair River was 68 000 cu. ft. per sec. less than the normal. The reserve storage of Lake Superior contributed 25 000, and Michigan-Huron, 28 000 cu. ft. per sec. The supply from the Erie and Ontario Basins was a little greater than normal. The outflow to salt water was at the rate of 234 000 cu. ft. per sec. Lake Superior by January 1, 1911, had fallen to Elevation 601.2± and Michigan-Huron to Elevation 579.33. Had super-regulation been in effect, these elevations would have been 601.8 and 581.3 ft., respectively. The gain of 2 ft. for vessel drafts in the St. Marys River and Lakes Michigan-Huron is significant. During 1911 the lakes would have risen slightly; and complete level restoration would have been accomplished in the generous supply year of 1912.

Mr. Sabin clings to the thought of single-river regulation illustrated by the works in St. Marys River—necessitated by water diversions—and suggests a tryout of regulating works in the Niagara River. Such works will help, but the principle to be followed if works are to be built in sequence is to build the lowermost works first; because the operation of works in the outlet of Lake Ontario cannot affect adversely the upper lakes. The operation of the Lake Superior outflow works has at times damaged the lakes below; and works in the Niagara River alone may damage Lake Ontario and the St. Lawrence River. Super-regulation, with works in the St. Clair, Niagara, and St. Lawrence Rivers making effective the existing works in the St. Marys River, is the sound engineering solution for the Great Lakes System. The cost of such works and the cost of operating them is negligible, because the vast financial importance of water transportation warrants adequate maintenance of this internal waterway, even aside from its ultimate destiny in overseas commerce.

Does the operation of the scheme of super-regulation require an intelligence transcending that required in the operation of a super-power system or other engineering work? Will "omniscience" be required, as suggested by Mr. Sabin? Four elements enter the problem: First, the release of a reasonably constant minimum volume of outflow through the regulating gates in the St. Lawrence River; second, the utilization of the forebays of Lakes Ontario and Erie as equalizing basins; third, the release of water through the St. Clair River to supplement the Erie and Ontario supplies in maintaining the fixed minimum volume of outflow through the St. Lawrence River; and, fourth, the operation of the reservoirs of Lakes Superior and Michigan-Huron as a unit of storage, with restrictions or enlargements of flow in the St. Marys River to keep the two basins in step with each other.

A detailed demonstration of the operation of the super-regulation of the Great Lakes System is beyond the limitations of this paper. The works to be utilized for outflow control do not need to be precisely detailed now. The writer would add to the works at the head of the St. Clair River a fourth expansion basin and navigable pass (see Fig. 5) to lessen current velocities and secure larger control volume.

No menace of unduly high water will exist in Lakes Erie and Ontario, because the relatively small areas of these lakes permit rapid disposal of surplus water by excess capacity channels; and these channels may be easily secured. Nor will any menace of unduly high water exist in Lakes Superior and Michigan-Huron, provided the base plane of control is conservative. Lake Superior has ample excess outflow capacity in lateral water-power canals. If a volume of 40 000 cu. ft. per sec. flows continuously through these canals, by-passing the rapids in St. Marys River (and this volume is never diminished), the value of the excess outflow capacity is unquestionable. And this same principle of continuous supplemental outflow creating excess capacity applies to the Chicago Drainage Canal and to the Welland Canal. Mr. Sabin questions the specific application of this principle.

Colonel Pillsbury raises the question of legality in stabilizing the levels of the lakes, suggesting that a riparian owner may insist on only the frequency of high-water periods shown by the hydrograph since 1860. The rights of riparians to natural sequences in lake levels and in volumes of river flow affect many engineering undertakings. In cases where the interests of shore owners in submerged lands clash with the necessities of navigation, the right of the riparian to compensation disappears. (See the case of United States *vs.* The Chandler-Dunbar Company.) The governmental right to modify the natural outflow of the St. Lawrence River in the interest of navigation and water power must be supreme.

The possibilities of the St. Lawrence Waterway to the Sea will continue to kindle the imagination. Some of the vital engineering principles are recorded in this paper.

Paper No. 1581

MUNICIPAL WATER SUPPLY PROBLEMS OF ATLANTA, GEORGIA*

By Paul H. Norcross,† M. Am. Soc. C. E.

With Discussion by Messrs. J. N. Chester and Wingfield Nisbet.

Synopsis

The water supply of the City of Atlanta, Ga., is of interest from several angles, as it is the largest development of a surface water supply in the Southeastern States, furnishes a water unusually free of dissolved solids and, therefore, peculiarly well suited for industrial uses, and contains, in addition, some unique features of design and operation.

The supply is derived from the Chattahoochee River, a Cherokee Indian name meaning the "Chatter", or "Hooting of the Owl". Its source is on the eastern slopes of the Blue Ridge Mountains, at elevations ranging from 3 000 to 4 000 ft., and it flows in a southwesterly direction, through a basin singularly free of pollution.

The supply works consist of a 48-in. intake conduit, a steam-operated river pumping station, having a capacity of 106 000 000 gal. per day, pumping against a maximum head of 275 ft., including friction, through three parallel conduits, 30, 36, and 48 in. in diameter, respectively, each approximately 18 500 ft. long, into two raw water or settling basins, having a combined capacity of 393 000 000 gal.

From the raw water basins, the water flows by gravity through a battery of five coagulating basins, having a combined capacity of 13 000 000 gal., and then to two gravity filtration plants, operated in parallel. One plant, the original installation, is of the pressure type, containing 48 units, 12 vertical and 36

* Presented at the meeting of the Sanitary Engineering Division, Atlanta, Ga., April 10, 1924.

† Cons. Engr., Atlanta, Ga. Mr. Norcross was drowned at the time of the sinking of the *Norman* in the Mississippi River on May 8, 1925.

horizontal, having a total rated capacity of 21 000 000 gal. daily, and the other, completed in 1923, a plant of equal rating of the reinforced concrete gravity type, having 7 units, making a total combined rated capacity of 42 000 000 gal. daily.

From the filtration plants, the water passes through a 60-in. conduit, to a new reinforced concrete covered reservoir, of 10 000 000 gal. capacity, which is cross-connected to a steam-operated high-service pumping station, having a rated capacity of 105 000 000 gal. per day, delivering water direct to the distribution system against a maximum head of 100 to 120 lb.

Some of the features of design and operation include both inverted and overhead siphons of the raw water conduit, either in tunnel or aqueduct; flexible operation of the raw water conduits, raw water basins, etc.; a new, open-gallery type filtration plant and appurtenances, and a new reservoir and turbo-centrifugal pumping units that have developed unusually high efficiencies for loads varying from 50 to 110 per cent.

The successful and economical operation in parallel of two widely different types of filter plants is worthy of comment.

The problem of keeping pace with increasing demands, due to the rapidly growing population and industrial, commercial, and municipal consumers, while maintaining service, is being accomplished without interruption thereof.

Introduction

The purpose of this paper is to describe briefly the history and development of Atlanta's municipally owned water utility which, because of its importance and certain unusual features of design and operation, seems worthy of attention, and also to stimulate renewed interest in the broad field of water treatment. This subject is of increasing importance, particularly in the southeastern section of the United States which, due to its equable climate, wealth of raw materials, wonderful agricultural possibilities, and growing economic advantages, is gradually assuming supremacy in many fields, including the textile industry, and where numerous other classes of manufacturers and commercial concerns are prospecting for locations.

The extent of domestic and industrial use of public water supplies in the United States has been the subject of an investigation by the United States Department of the Interior, and the result of this study is set forth in a paper entitled "Utility of Public Water Supplies in the United States",* which publication is a most valuable addition to water supply data. This paper serves to emphasize the value of water free of minerals especially in industrial lines, including boiler plants, and "the manufacture of soft drinks, bakery products, and other foods." As Atlanta is the "birthplace" of probably the most widely known "soft drink" manufactured to-day, the significance of this statement is obvious.

It is, of course, needless to emphasize the importance of a high sanitary quality for public water supplies, or to review the decrease in "typhoid toll", due to advance in the science of water treatment. It is worthy of note, how-

* *Water Supply Paper No. 496*, U. S. Geological Survey.

ever, that the growing and more exacting demands of the consumer of to-day is for water not only free of suspended matter and polluting organisms, but also one more acceptable from the standpoint of mineral content.

The distribution of "hard" and "alkali" waters of various degrees of hardness throughout the country is general, occurring in twenty-seven States, comprising probably 75 to 80% of the total area of the United States. The localities providing so-called "soft water" are confined to nineteen States located in three groups, situated in the Northwest, Northeast, and Southeast, respectively, with the last predominating in area. Georgia occupies the geographical center of this latter area. That part of those States in the Southeast above the coastal plain obtain their supplies principally from the eastern and southeastern slopes of the Blue Ridge and Appalachian Mountain Ranges, and Atlanta's supply ranks foremost in size and character of development in this group.

It is not intended to review in detail or to describe, except briefly, those parts of the utility which are commonplace, but it is the desire of the writer to present a comprehensive view of the problem and to describe such parts of the development as seem interesting and unusual.

Historical

The real history of Atlanta's water utility originated in 1872, when the first Water Commission of the city contracted for the construction of a water supply on the head-waters of a stream having its source within the city limits, flowing in a southeasterly direction, and being a tributary of the Altamaha Drainage Basin, with its outlet in the Atlantic Ocean.

This supply consisted of an impounding reservoir on the head-waters of South River, about 3 miles south of the center of the city, of 250 000 000 gal. capacity, covering an area of 51 acres, with a drainage area of approximately 5 sq. miles. The water from this supply was originally untreated but, about 1886-87, Hyatt pressure type filters were installed (probably one of the first pressure type installations in the United States), from which the water was collected in a clear-water basin having a capacity of 800 000 gal. and then pumped direct to the distribution system by steam-driven Holly quadruplex type pumps, one of 2 000 000 and the other of 4 000 000 gal. daily capacity.

This supply, the first water from which was pumped into the mains on September 8, 1875, was supplemented in 1884 by an Artesian well, located in the center of the city, which was drilled through about 2 000 ft. of granite, or gneiss—the underlying bed-rocks of Atlanta. This well produced a limited supply of water from four veins, 102, 225, 450, and 1 160 ft. below the surface, respectively.

Records of water used daily and annually prior to 1888 are very meager, but the total quantity pumped from South River during that year was 629 000 000 gal., supplemented by 10 500 000 gal. from the Artesian well supply, which latter quantity represented the total available from this source. It is interesting to note that all domestic consumers were metered in 1888, and that a uniform charge of 17 cents per 1 000 gal. was made.

As a part of the drainage area of South River was within the city limits, and as unusual growth of the city began between 1880 and 1890, it was soon obvious that South River water, although originally of unusually good quality, was becoming grossly polluted. In addition, the supply available from this stream, with its limited drainage area, was not adequate to meet the existing and increasing demands made upon it. It, therefore, became necessary to obtain another and more ample supply.

In 1889, the city officials engaged the late Rudolph Hering, M. Am. Soc. C. E., to make surveys, investigations, and report on a new supply. Mr. Hering's report submitted under date of October 15, 1889, recommended the development of a supply from the Chattahoochee River. This stream has a drainage area of about 1 500 sq. miles with its head-waters in the Blue Ridge Mountains of North Georgia. It is a tributary of the Apalachicola Drainage Basin and flows in a southwesterly direction into the Gulf of Mexico, which course brings it, at its nearest point, within about 6½ miles northwest of the center of the city. This stream, although carrying large percentages of turbidity during certain periods and nearly always highly colored with clay and silt, was of splendid quality, with only nominal pollution and with a chemical analysis indicating a water almost free of mineral content.

The analysis of Chattahoochee River water, as made by the U. S. Geological Survey, is shown in Table 1.

The topography of Atlanta is peculiar and interesting. It consists of a series of ridges averaging 950 to 1 000 ft. above sea level, that divide the drainage of streams flowing either into the Atlantic Ocean or the Gulf of Mexico. This is an advantage from a sanitary standpoint, but the deep valleys and high ridges naturally affect the pumping problem and add to the cost.

Mr. Hering recommended the construction of a pumping station on Chattahoochee River, with an intake at the point at which it is at present located, just above the confluence of Peachtree Creek, as this latter stream drained a large part of the area within the city limits, and the construction of raw water storage reservoirs, treatment plant, and a high-service pumping station about half way between the river and the center of the city. The point on the river selected for development was about 300 ft. lower in elevation than the highest ridges in the city, thus making necessary two pumping stations to provide adequate pressures. Table 2 gives the elevation of points in the city and on the river.

The wisdom of selecting the Chattahoochee River as the source of the ultimate and final supply for Atlanta has been proved. The character of the region at its source, consisting of unpopulated mountain ranges between 3 000 and 4 000 ft. above sea level, with unusually high annual rainfall, and the fact that it flows through a sparsely settled area and drains practically no towns or cities of size, combined with the excellent chemical quality of its water, are factors in its favor.

TABLE 2.

Fig. 1 shows the drainage area of the Chattahoochee River at the intake. It will be noted that no large towns are in its basin. The diagram also shows the location of the South River development—the original public water supply of Atlanta—and the present outlines of the city limits.

Original Plant

The City began the development of Chattahoochee River in 1891 and placed the new supply in service in September, 1893. The original development consisted of a gravity-operated, 48-in. cast-iron pipe intake about 700 ft. long, discharging into an open intake well, and a brick pumping station surrounded by an earth dike to prevent flood overflows. Steam-driven Holly horizontal compound pumps, operated against a suction lift of about 16 ft., delivered the water through a 30-in. cast-iron main, about 18 500 ft. long, to an unlined raw water storage reservoir of 177 000 000 gal. capacity constructed in cut and fill and by damming several ravines.

The water was then passed by gravity through concrete coagulating basins to a battery of horizontal pressure type filters, operated as closed gravity filters with an average operating head of 30 ft., and thence to an uncovered clear water well. The total loss of head between high-water level in the raw water reservoirs and the high-water line in the clear water well was 40 ft. From there, the water was conducted to the high-pressure pumping station known as the Hemphill Avenue Station. The reservoirs, coagulating basins, filter plant, and pumping station were located on the main line of the Southern Railway about three miles northwest of the center of the city. This station was similar in type, design, and equipment, to the South River Station.

It is interesting to note that the old Hyatt filters, twelve in number, which were of the vertical pressure type, were removed from the South River Station and installed, and operated in parallel, with the horizontal filters at the new plant.

Plant in 1920

Between 1893 and 1920, this plant was expanded along the lines of the original development and, in 1920, the pumping equipment at the Chattahoochee River Station consisted of two 10 000 000-gal. Holly horizontal compound pumps, one 18 000 000-gal. Holly horizontal compound pump, one 10 000 000-gal. Worthington motor-driven centrifugal pump, and one 28 000 000-gal. DeLaval turbo-centrifugal pump, the last having been installed in 1918-19, to meet emergency war demands due to the construction of Camp Gordon, near Atlanta.

The raw water conduits consisted of the original 30-in. and an additional 36-in. cast-iron main, delivering water against a head of 260 to 290 ft., including friction, to two raw water reservoirs with capacities of 177 000 000 gal. and 216 000 000 gal., respectively.

The treatment plant consisted of five coagulating basins having a combined volumetric capacity of about 13 000 000 gal., and the filter plant contained thirty-six horizontal type pressure units of 500 000 gal. daily capacity each, and twelve Hyatt vertical type pressure units with rated daily capacities of 250 000 gal. each, making a total combined rated capacity of 21 000 000 gal. daily, discharging into two circular, open-type, clear water wells having a combined available capacity of 2 000 000 gal.

The Hemphill Avenue, or High-Service, Station, contained two 10 000 000 and one 15 000 000-gal. horizontal compound pumps, one 20 000 000-gal. vertical triple expansion pump, and one 30 000 000-gal. DeLaval turbo-centrifugal pump installed in 1920.

A brief résumé of the demands of service and the capacities of several of the elements composing the plant in 1920 should aid in a clear understanding of the major problems that confronted the city at that time. These are shown in Table 3.

TABLE 3.

	Gallons daily.
Average rate of consumption (1920)	24 000 000
Maximum rate of consumption (1920)	40 000 000
Maximum capacity of supply mains from river (1920)	33 000 000
Rated filter capacity (1920)	21 000 000
Clear-water storage (1920)	2 000 000

In addition to the fact that parts of the plant were wofully inadequate in size and arrangement to meet existing demands, much of the equipment had reached the end of its useful life, or was inefficient and obsolete.

Investigations and Studies

In 1920, the City of Atlanta authorized complete surveys and investigations to determine the necessary improvements and extensions to the water supply of the city. This investigation included study of the river intake, the pumping station at Chattahoochee River, supply mains between the river and raw water reservoirs, coagulating basins, filter plant, and high-service pumping

station, including all connections and appurtenances. These studies were started in the latter part of 1920 and extended through 1921 and, as a result, recommendations were made, which briefly were as follows:

(*a*).—Construction of an impounding dam, new intake, and pumping station to supplement the existing intake and station.

(*b*).—Remodeling of the Chattahoochee River Station, including additions and changes in the boiler plant, remodeling of steam headers, new chimney, installation of new and efficient pumps, and the re-arrangement of suction, discharge lines, and headers.

(*c*).—New raw water supply main from the River Station to the raw water reservoirs, paralleling the existing 30 and 36-in. mains.

(*d*).—Installation of gate-house and cross-connection, controlling and making more flexible the operation of the raw water reservoirs.

(*e*).—Construction of a mixing chamber and a new chemical house for the proper treatment of water prior to coagulation and filtration.

(*f*).—Addition of a filter plant of the gravity type to the existing filter plant and the construction of a covered reinforced concrete clear water reservoir of ample size to meet peak demands, constructed at a higher elevation than the old reservoirs to reduce cost of pumpage, and the abandonment of the old clear water reservoirs, except for use in emergencies.

(*g*).—Remodeling of the Hemphill Avenue, or High-Service, Station, including changes in boiler plant, new chimney, remodeling of steam headers, and the installation of new and efficient pumping equipment, and re-arrangement of suction and discharge lines.

The foregoing recommendations were the result of an extensive study and investigation of the physical plant and operating costs and records, supplemented by studies of population, pumpage, consumption rates, and forecasts of future demands. (See Figs. 2, 3, and 4).

It is worthy of mention that although the demands on the water-works had outgrown the plant, the sanitary quality of the treated water furnished the consumers had remained, with few exceptions, at a high average. Red or colored water, however, was becoming more frequent, and it was obvious that the intake facilities, raw water pumping plant, raw water supply mains, pre-filtration and coagulating facilities, filter plant, and clear water storage had reached their ultimate capacities, and that the high-pressure pumping station needed early attention. A break-down at any one or more points would have precipitated a water shortage with disastrous results.

The preliminary cost estimates of the proposed improvements approximated $4 600 000, which included an item of $150 000 for the extension of mains within the city. Due to the customary impecunious condition of municipal treasuries, and the crying needs of other city departments, the amount provided for these water-works improvements was only $3 100 000, of which $250 000 was to be provided by a special tax assessment and $2 850 000 by a bond issue.

All these funds, except about $100 000, were made available in November, 1921, and in January, 1922, the actual construction work began. With the

exception of certain items of the improvements that are not yet under construction, due to delays and the failure to provide funds, several of the major improvements are either completed and in operation, or will be within short time.

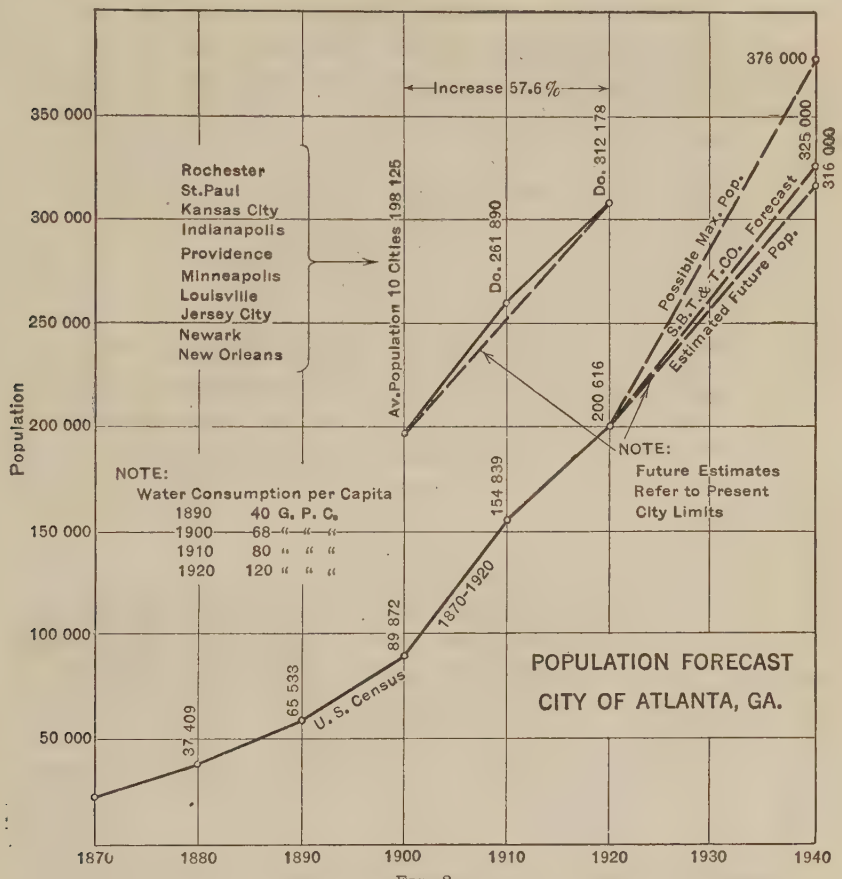

FIG. 2.

DESCRIPTION OF IMPROVEMENTS

New Intake and Impounding Dam.—The present intake which consists of one line of 48-in. cast-iron pipe terminating in a brick pier, with iron grating inlets, located in the bed of the river, is not submerged completely at all periods, as low-water conditions often partly uncover it. The normal water level of the stream has been raised by constructing a rip-rap and a pile dam, but due to increasing demands, it is extremely important that new intake works be provided at the earliest possible date. The present intake line is poorly located and crosses under Peachtree Creek, a stream that flows into the river just below the intake, and is otherwise not susceptible of much improvement. However, within 2 miles up stream, there are several ideal locations for the new intake works. When the new intake is constructed, the

FIG. 4.

City will also build an impounding dam to provide necessary storage to meet future requirements during low-water and heavy draft periods. The Chattahoochee River, due to its mountain source and the characteristics of its basin and run-off, has wide fluctuations of flow. This variation is further complicated by a hydro-electric plant about 11 miles up stream, which impounds water at night and discharges through its water-wheels during daylight hours. These factors emphasize the necessity for an impounding dam. The head created by this dam will reduce the pumping lift and provide hydraulic power which will be utilized by the City for pumping, thus reducing operating costs. The construction of the new dam and intake, with connections to the Chattahoochee River Station, has been delayed by negotiations between the City and riparian owners and the usual lethargy of municipalities in providing the necessary funds.

It is proper to state here that the selection of the original intake and pumping station sites was probably influenced by considerations of economy and expediency. The fact remains, however, that the present arrangement and design preclude additional expansion along good engineering lines. The location of the pumping station about 25 ft. below the flood-plain of the river, thus requiring the maintenance of dikes and emergency attention to prevent flooding through the intake well at high-water periods, supplemented by the fact that the sole dependency for supply is on one single inlet separated from the pumping station by an intervening stream, is a condition requiring prompt correction.

Remodeling Chattahoochee Station and Appurtenances.—To provide capacities, economies, and flexibility, and, at the same time, maintain service, it was found necessary to make radical alterations and extensions and additions to the Chattahoochee Station. These improvements consist of a new radial brick chimney, changes and additions to the boiler plant, re-arrangement of steam headers, abandonment and removal of the two 10 000 000-gal. pumps and the one 10 000 000-gal. motor-driven unit, installation of efficient pumping units, remodeling of suction and discharge lines and headers, and the reconstruction of the interior of the pumping station.

Practically all this work has been accomplished without interruption of service, and the present equipment of the Chattahoochee Station consists of the following:

One boiler plant, having a rated capacity of 1 850 h.p.
One 18 000 000-gal. compound condensing Holly unit (installed in 1904).
One 28 000 000-gal. DeLaval turbo-centrifugal unit (installed in 1919).
Two 30 000 000-gal. DeLaval turbo-centrifugal units (installed in 1918-19).

All the pumps lift water from the open suction well and discharge either into a new 48-in. header, or directly into the raw water supply mains.

The two 30 000 000-gal. turbo-centrifugal units were purchased in competition with 15 000 000-gal. turbo-centrifugals and reciprocating units. The load on the Chattahoochee Station is constant and susceptible of little varia-

tion, consequently, the use of smaller units represented no economy. The guaranties made by the successful bidder were based on the use of steam at 175 to 190 lb. pressure, with 100° superheat, and are as follows:

110% load	163 400 000	ft-lb. per 1 000 lb. of steam
100% load	166 000 000	" " " " " "
75% load	151 000 000	" " " " " "
50% load	126 900 000	" " " " " "

The units were completed in the fall of 1923. Duty tests were made on them during the latter part of December, 1923, and in January, 1924; in all these tests they have met or exceeded their guaranties and are notable examples of recent development in this type of equipment.

The re-arrangement of the suction and discharge lines provides ample facilities for flexible operation and increased demands. These lines are arranged with the idea of preventing interruptions of service from accidents and other emergencies. In addition, the station is provided with indicating and recording instruments to facilitate efficient operation, and the keeping of proper records.

The present intake facilities have not been increased, principally because the arrangement and physical location are poorly suited for further development. The capacity of the 48-in. cast-iron intake is limited by its size and the head of water over its inlet, which head, as previously stated, varies not only during the wet and dry seasons, but fluctuates daily and hourly due to the existence of the hydro-electric plant of the Georgia Railway and Power Company at Morgan Falls, several miles up stream, which stores the water at night and discharges during the day.

The problem of increasing the water level over the intake is complicated by the existence of a shifting sand-bar, or island, in mid-stream, known as DeFoor's Island, just opposite the water-works plant. In years past, the elevation of the water over the inlet of the intake had been increased by the construction of a rip-rap dam between the east bank of the stream and the Island, and a pile dam with rock-fill, between the north point of the Island and the west bank of the stream. During 1924, additional rip-rap will be added to the existing dams to increase the water level, but this will provide only temporary relief, as it will be necessary to supplement this intake by the construction of another one which will be located up stream at a more suitable site.

New 48-In. Cast-Iron Raw Water Main.—The necessity for new raw water supply conduits was emphasized by the fact that the peak demand which was increasing, exceeded the combined daily capacities of the existing 30 and 36-in. cast-iron mains. Detail surveys of existing and available routes and study of the future demands showed the advisability of installing an additional raw water main not less than 48-in. in diameter, along the same route as the existing mains from the Chattahoochee Station to the raw-water reservoirs.

After receiving competitive bids on steel, reinforced concrete, and cast-iron conduits, the last was selected. The conduit was constructed in sections

and placed in operation as each section was completed. It is now finished and in operation. Construction of this line was somewhat complicated and delayed by the necessity of crossing the tracks of three railroads and two interurban electric railways. Inverted siphons were used under two of the railroads, one siphon crossing eleven tracks and the other nine. The problem of maintaining water-tight conduits was perplexing and constituted a perpetual hazard with an economic loss due to constant leakage and occasional breaks.

The delay in the completion of these railroad crossings was due to a long series of conferences with the railroad officials as to the merits and costs of underground conduits in open cut or tunnels, and overhead crossings, and the existence of previous contracts between the City and the Railroad Company, which required the Railroad Company to pay for maintenance. Eventually, new and equitable contracts were executed, and the remaining portion of the new 48-in. main, between the Chattahoochee River and the raw water reservoirs, is now complete. Fig. 5 is a view of the pipe gantry used in laying the 48-in. cast-iron main.

Some of the more interesting details of this main include the construction of a differential surge tank at the high point on the line, with individual connections to the 30, 36, and 48-in. mains; and the elimination of one of the inverted siphons of both the existing and new mains by the construction of an overhead aqueduct, consisting of a steel span with steel girder approach on one end and a reinforced concrete span on the other end, carrying two lines of 48-in. cast-iron pipe, over the tracks of the Seaboard Air Line Railroad. Fig. 6 shows the differential surge tank and a view of the raw water mains.

The new main is also cross-connected with the 30 and 36-in. mains at four intermediate points with numerous fittings and gate-valves, which permit economical repairs with a minimum loss of time and also provide flexibility of operation.

Gate-House and Cross-Connections, Raw Water Reservoirs.—Previous to 1921, the physical connection between the raw water conduits and the two raw water reservoirs was very limited. To provide flexible operation of the two basins and also permit the lowering of the level of one or both without undue delay, new cross-connections with a centrally controlled gate-house were planned. This was all the more necessary in view of the increased capacities that were being provided by the installation of the new 48-in. raw water main.

As designed and constructed, the gate-house located between the two reservoirs, receives the water from the three raw water conduits through two 48-in. inlet pipes discharging into a common well of reinforced concrete construction. This well is cross-connected by a cast-iron pipe conduit 60 in. in diameter to the raw water reservoirs, the invert of which is 7 ft. below the normal high-water surface of the basins.

The raw-water inlets and the outlets to the two reservoirs are controlled by two 48-in. and two 60-in. sluice-gates, electrically operated, with hand-wheel

connections for emergency, all of which is housed in a substantial brick building.

Mixing Chamber and New Chemical House.—The pre-filtration processes of water treatment have grown in importance and magnitude in recent years. More extensive and detail operating records, supplemented by technical data obtained from numerous tests and investigations stimulated by various agencies, have emphasized the necessity for more scientific and comprehensive methods of preparing the water for filtration.

The Chattahoochee River carries variable and, sometimes, large quantities of suspended matter so finely divided that it will not settle even after a long period. It is necessary, therefore, to treat the water with a coagulant, which facilitates the removal of this finely divided material in coagulating basins. The process generally consists of injecting a solution of aluminum sulfate which due to the normal alkalinity of the water produces the usual flocculent precipitate and deposition of the suspended matter. Good coagulation cannot always be obtained by the use of this chemical alone, as chemical and physical changes in the water, supplemented by the large range of turbidity content due to heavy rainfalls, etc., prevent the adequate formation of the flocculent precipitate and, consequently, the delivery of unclarified water to the filters. In many instances these changes take place rapidly. The effect of these changes are of more importance particularly in water similar to that of the Chattahoochee River, containing a small quantity of dissolved solids.

These varying factors affecting the Chattahoochee River water, including reduction in alkalinity content and intensity of acidity—expressed as the hydrogen-ion concentration—supplemented by high turbidity, have often caused the delivery of discolored and unsatisfactory water to the distribution system, as the failure to clarify the water properly in the coagulating basins and the delivery of partly treated water with a large quantity of suspended matter to the filters, interferes with their normal operation.

The reaction between aluminum sulfate and the carbonate or bi-carbonate of natural waters often sets free a quantity of carbon dioxide, thus making the intensity of acidity great enough to cause corrosion in iron pipes and consequently red water. This is unfit for use by both the domestic and industrial consumer and will eventually damage the pipes.

The facilities for chemical treatment in 1920 were housed in a small brick building, at one end of the coagulating basins. In addition to the chemical and bacteriological laboratory, this building housed two wooden tanks for chemical solutions and provided storage space for alum, lime, etc. Normally, the alum solution was delivered by gravity through two parallel lines of lead pipe about 500 ft. long, to the 60-in. raw water conduit conducting the water from the raw water to the coagulating basins. Facilities for providing artificial alkalinity consisted of emergency preparations of solutions of soda ash, or lime, in one of the chemical tanks. This "hit-or-miss" method, without properly designed structures and equipment, has been the source of much trouble in the treatment of water at Atlanta. In 1921-22, the City installed a dry feed machine for applying lime, at a point adjacent to the 60-in conduit. When the new filter plant was placed in operation, it was necessary to re-

Fig. 5.—View of Pipe Gantry for Laying 48-Inch Main, Lead Gantry in Background, Atlanta, Ga.

Fig. 6.—View of Differential Surge Tank; Raw Water Mains, Atlanta, Ga.

arrange the operation of the coagulating basins and advisable to abandon the method of injecting the alum solutions, as inadequate mixing and other factors were preventing the proper removal of suspended matter.

In 1923, a small temporary wooden building for housing two alum tanks and the dry feed lime machine was constructed at the outlet tower of Raw Water Basin No. 2, and experiments were made in the injection of chemical solutions into the entrance of the 60-in. raw water conduit to the coagulating basins. The results obtained justified the change; but the necessity for a structure to facilitate proper mixing under varying conditions prior to coagulation still exists, as occasionally "red" and "muddy" water is produced by the filtration plant.

After careful investigation and study, it was decided to install a gravity-operated mixing chamber, between the raw water and coagulating basins, with a chemical house superimposed over the inlet to the mixing chamber. The design contemplates a structure built in three sections, which can be operated at rates of 30 000 000, 45 000 000 and 60 000 000 gal. per day, respectively, with the detention time element ranging from 7 to 45 min. The length of travel for the several rates of application varies from 1 200 to 3 000 ft., with velocities ranging from 1.8 to 3.45 ft. per sec.

The design gives a most flexible and satisfactory arrangement and will eliminate the delivery of unsatisfactory water to the filters. Bids have been received and work on this structure which is to be reinforced concrete with cast-iron pipe influent and effluent conduits, is to be started as soon as the steps necessary to legal condemnation of the necessary land area are completed.

New Filter Plant and Clear Water Reservoir.—The pressure type filters of the existing filter plant having a combined rated capacity of 21 000 000 gal. per day, discharged into two open circular clear water wells of a combined capacity of approximately 2 000 000 gal. The elevation of water in the coagulating basins is 985.0 and that of the water surface in the clear wells, 945; therefore, 40 ft. of head was lost in operation.

Because of the daily demands in excess of the normal rating of the filters and the limited capacity of the clear wells, it was necessary to vary the rate of filtration to meet the fluctuations in rate of draft or pumpage, and this constant change of the filtration rate, together with the overload on the filters which was approximately 100% during periods of peak demand, was often reflected in the delivery of a discolored and partly purified water. The maximum rate of draft had reached 40 000 000 gal. per day in 1920, and the maximum rate of filtration through the pressure filters had reached approximately 250 000 000 gal. per acre per day. It became imperative, therefore, to construct additional filters and a clear well of sufficient capacity to permit a more uniform filtration rate.

It was decided to construct a covered clear water basin of 10 000 000 gal. capacity, and a gravity filter plant of 21 000 000 gal. daily capacity designed for future expansion to 60 000 000 gal. per day. Construction was started March, 1922, and the new plant was placed in operation in July, 1923.

The water surface of the new filters was at Elevation 977, or 8 ft. below the high-water elevation of the coagulating basins, in order to provide for

loss of head in operating and a draw-down capacity of raw water and coagulating basins for future pre-filtration processes and emergencies.

The high-water elevation of the new clear water basin was at 967, or 10 ft. below the water surface in the filters. This elevation was 22 ft. higher than that of the water surface in the old clear water wells and necessitated the abandonment of these wells. The total loss in head through the filter plant now became 18 ft., and a saving of 22 ft. of head was obtained.

This higher elevation did not, however, render the pressure type filters inoperative, because a differential of 18 ft. with full clear water basin still existed, and this head is more than enough to operate them at their normal rate.

The filter plant (Figs. 7 to 11) consists of seven 3 000 000-gal. daily units, arranged in a straight line with an open pipe gallery. They are of reinforced concrete, 28 by 42 ft. in plan, have a net sand area of 1 040 sq. ft., or 0.0239 acre each, and are designed to operate at the rate of 125 000 000 gal. per acre per day. Each filter is equipped with twelve concrete wash-water troughs, 7 ft. center to center, which discharge into a central drain dividing the filter into two parts. The walls of this drain are 6 ft. high and carry a concrete walkway which extends from the operating platform to the rear of the filter. (See Figs. 8 and 10.)

The under-drain system consists of a cast-iron manifold, 10 in. in diameter, divided into eight sections and having eight 10-in. outlets to the effluent main. The laterals are of 2½-in. cast-iron pipe spaced 6 in. center to center. Laterals are drilled in the bottom quadrant with ⅝-in. holes at an angle of 45°, center to center, and staggered. (See Fig. 8.)

The sand bed is 30 in. deep, and the sand has an effective size of 0.36 mm. and a uniformity coefficient of 1.5. The gravel supporting this sand is placed in five layers and is 20 in. deep.

The filters are entirely covered with a brick superstructure, 76 by 202 ft. At the west end of the building (Fig. 7) is located a head-house, laboratory, and office, 60 by 76 ft., which eventually will occupy a central position when the plant reaches its ultimate capacity.

The coagulated water enters at the west end of the plant through a 48-in. cast-iron main and Venturi meter. The level of water on the filter beds is controlled by a 42-in. hydraulic valve set in this line, which is operated by a float and pilot-valve mechanism set on the operating platform in an open chamber, 3 by 4 ft., connected with the coagulated water conduit. This chamber is also equipped with an emergency overflow weir and is connected with the main drain conduit to prevent the overflow of the filters if the control valve fails to operate.

The four main conduits in the filter building below the filter gallery are of reinforced concrete, side by side, and were poured monolithic in sections in one operation. These conduits were designed for an ultimate capacity of 60 000 000 gal. per day. The tops of the conduits are level with and form a part of the lower floor of the building. The bottom of the filters is about 5 ft. above this floor and is supported on concrete columns.

FILTER PLANT
STRUCTURAL DETAILS

FIG. 9.

All collector piping beneath the filters is exposed and easily accessible. The under-side of the filters is shut off from the main part of the building by a 6-in. concrete curtain-wall, but a door is provided for each filter.

All operating piping, hydraulic valves, controllers, etc., are exposed to view from the main floor and are arranged so that all are readily accessible for repair or adjustment. This arrangement is perhaps somewhat greater in first cost than the usual pipe gallery with filters on both sides, but it certainly results in more efficient operation and permits inspection and ease of maintenance because of its accessibility. The operating platform is 15 ft. wide, and is supported above the conduits by concrete columns. It is reached from the main floor by a concrete stairway in the center, and by circular steel stairways at both ends, of the building. Fig. 11 is a view of the influent, effluent, wash, and drainage connections.

Wash water is supplied to the filters by a reinforced concrete wash-water tank of 425 000 gal. capacity, located about 50 ft. north of the filter building, with the normal water surface at Elevation 1 000, or 23 ft. above the water surface in the filters. Filtered water is supplied to this tank by two 4 000-gal. per min. motor-driven centrifugal pumps arranged in duplicate. The pumps take suction from a well connected to the main effluent conduit and are automatically controlled by float switches in the tank and suction well. The pump intake is arranged so that the water in the effluent conduit cannot be drawn down below the outlets of the filters, which would break their seals.

The tank discharges into the wash-water conduit through a 30-in. cast-iron main in which is set a 30-in. Builders Iron Foundry controller. The register for this controller is mounted on the operating platform and indicates the rise of wash water in the filters, in inches per minute and in gallons per minute, and records the time, duration, and rate of wash. A change in the rate of wash can be quickly and easily made by adjusting the instrument. It also prevents a sudden rush of water due to quick opening of the hydraulic valve on the wash-water main, because the normal position of the controller is closed, and it requires at least 1 min. to open it.

The effluent from the filters enters the filtered water conduit through a 16-in. cast-iron line in which is set a 16-in. Builders Iron Foundry controller. The effluent conduit is sealed by a weir to prevent the lowering of the water below the filter outlets when the clear-water reservoir is drawn down below the effluent conduit.

At the east end of the filter building, chlorine is injected into the filtered water, and the water then passes through a 60-in. cast-iron main through a Venturi meter and a controlling gate-house to the clear water basin, or the pumps, the clear water reservoir floating on the line.

In the gate-house are located the various valves for controlling the flow from the clear water well and the filters. The 60-in. line is here reduced to 48 in. in order to decrease the valve cost and make operation easier. All valves have been arranged for electrical operation in the event this becomes necessary or advisable in the future.

The pressure filters have been connected to the clear water basin, and the effluent line from the new filter plant, and the supply line between the gate-

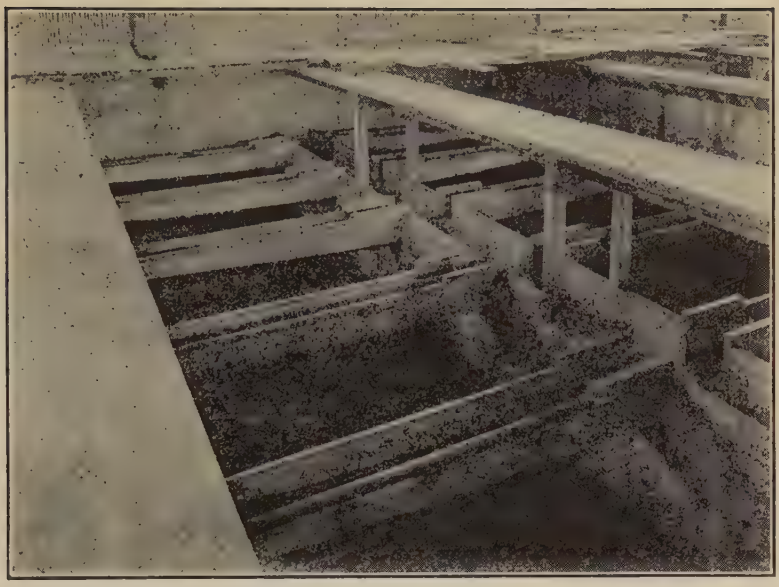

FIG. 10.—WASH-WATER TROUGHS, NEW FILTERS, ATLANTA, GA.

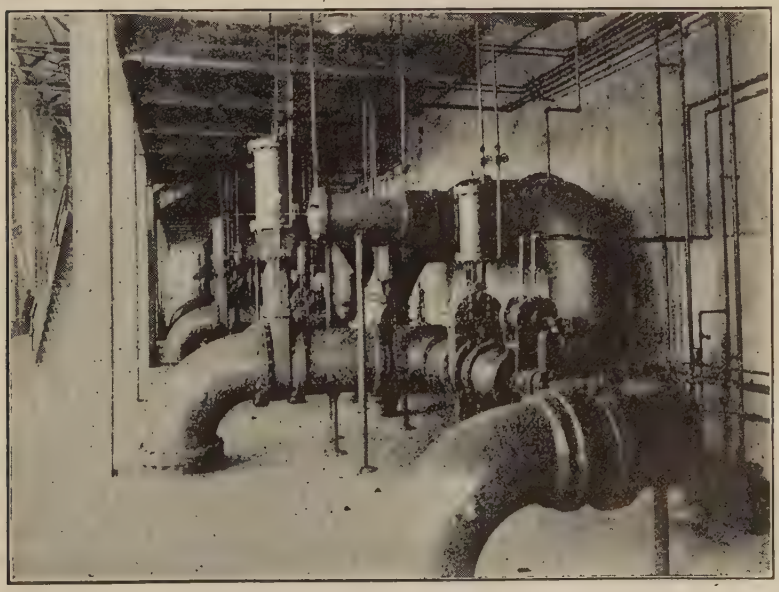

FIG. 11.—INFLUENT, EFFLUENT, WASH AND DRAINAGE CONNECTIONS, NEW FILTRATION PLANT, ATLANTA, GA.

house and the high-service pumps. Provision has also been made at the valve-house for an additional suction main to be laid in the future. When this is constructed, there will be two 48-in. and one 36-in. suction lines to the high-service pumping station.

The operation of the pressure filter plant in parallel with the gravity plant is accomplished by connecting the effluent from the pressure plant to the conduit conducting the water from the new clear water basin and gravity plant to the high-pressure pumping station, by a 36-in. cast-iron main. The pressure filters are located at Elevation 945, and the water surface of the clear water reservoir is at Elevation 967. To prevent back pressure on the pressure filters when the clear water basin is full, a check-valve has been inserted in the 36-in. line. The pressure filters must build up sufficient head to open this check-valve against the pressure from the new clear water basin, or the pressure from the gravity plant, before the filtered water from the pressure plant can pass into the system. With a full clear water basin a maximum differential of 18 ft. exists between the influent and the effluent, and this head has been found sufficient to overcome the losses due to the filters and pipe friction and to permit the operation of the pressure filters at their normal capacity in parallel with the gravity plant.

The old filter plant has no loss-of-head gauges, or rate-of-flow controllers, and the filters are washed by coagulated water. Detail plans for these improvements, including connection to the new wash-water tank of the new filter plant, have been prepared, and bids received, but contracts have not yet been awarded. This improvement is most necessary, and will probably be carried out during 1925.

Clear Water Reservoir.—The clear water reservoir has a capacity of 10 000 000 gal. It is trapezoidal in plan, 215 by 388 ft. at the top with 2 to 1 slopes, 22 ft. deep, constructed entirely in cut, and has a reinforced concrete roof of slab-and-beam construction which is covered with 18 in. of earth.

Small entry houses are provided at both ends of the structure, and concrete stairs extend along the slopes from the entry houses to the bottom of the reservoir. Fig. 12 is a view of the interior of the new clear water reservoir.

The floors and slopes are of concrete 6 in. thick and reinforced with electrically welded steel fabric of No. 4 wire, 4 in., center to center. In order to insure water-tightness, concrete beams or sills, 12 by 12 in., were first poured on the side slopes, 18 ft., center to center, with the tops of the beams level with the under-side of the slab. Into these beams, at intervals of 6 ft., were inserted bolts to hold forms. Bulkheads were erected on the center line of beams, and the slabs were then poured with a moderately wet mix, the forms being carried up 18 in. in advance of the concrete. Three slabs were usually poured simultaneously, and in this way the pressure on the forms was kept within reasonable limits. At the joints in the slabs over the beams, No. 18 gauge, galvanized-iron strips were inserted, extending 4 in. into the adjoining sections. Before the adjoining section was poured, the joint was covered with $\frac{1}{8}$ in. of hot pitch.

After completion, tests extending over a period of 20 days indicated a drop in water level with full reservoir of 3/32 in. per 24 hours. Some of this leakage was traced to the 48-in. valve in the discharge line from the reservoir.

Water enters and leaves the basin at the south end through a 60-in. cast-iron pipe laid under the floor, which is later reduced to 48 and 36 in. From this line are taken three sets of 24-in. cast-iron laterals which extend at right angles to the main conduit and discharge at the foot of the side slopes. These laterals are fitted with 90° bends and extend about 2 ft. above the floor of the basin. The bends on each pair of laterals are turned in opposite directions to facilitate circulation.

The clear water basin acts as a balancing unit for the filters, and the filter plant is now being operated at a uniform rate of approximately 26 000 000 to 30 000 000 gal. daily, the new plant supplying 21 000 000 gal. and the pressure plant the difference.

Operating Results

The new filter plant (Fig. 13) has been in operation since June, 1923, and the results produced from both the bacterial and the operating standpoint have been excellent, except when the water delivered to the filter plant was overloaded with suspended matter. The operation of the filters at a uniform rate has reduced some of these troubles, and, although the pre-filtration processes are seriously in need of improvement, the entire plant is now functioning much more satisfactorily than it did under a constantly changing rate.

There has been no evidence as yet of the formation of mud balls, or cracking or shrinkage of filter beds, and the distribution of wash water is quite uniform, which indicates that the design of the under-drain system is satisfactory.

Table 4 is a daily operating log of the plant for the six-month period ending January 31, 1924. These data indicate unusually good results, but inasmuch as they are the combined record of both the old pressure type and new gravity filter plant, they do not show some of the more interesting records of the operation of the latter plant.

The average length of run between washings of the gravity units varies from 60 to 70 hours, with maximums of more than 120 hours. The quantity of wash water required for these units has been less than 1 per cent.

The open type filter gallery with its ease of inspection, operation, and maintenance, justifies this type of design.

The new plant is provided with every facility and is heated from the boiler plant at the high-service station. Ample radiation produces satisfactory temperature during zero weather, which occurs very rarely.

Improvements at Hemphill Avenue Pumping Station (High Pressure)

The improvements at the Hemphill Avenue Station consisted of a new radial brick chimney with a steel flue for future extensions; remodeling the steam headers; equipping the boilers with superheaters and mechanical stokers; installing a de-superheater to provide saturated steam for certain units; remodeling of suction and discharge headers; removing one of the old 10 000 000-gal. pumps; and installing one 30 000 000-gal. turbo-centrifugal DeLaval

Average rise, in inches per minute	24.7	11.2	Minimum " " " " 19.7 in.

pumping unit, having practically the same guaranty as those at the Chattahoochee Station.

As this station pumps directly into the distribution system with no equalizing reservoir, the operating conditions are variable, the domestic demand ranging from a rate of 17 000 000 to 18 000 000 gal. per day at night to a rate of 45 000 000 to 50 000 000 gal. per day peak rate during daylight hours, and varying with the season of the year.

The construction of the new clear water reservoir (high-water elevation, 967) has placed all pump suctions under a positive head, which reduces the differential between water surface and maximum head, thus materially reducing unit pumping costs.

The average domestic pressure maintained at this station ranges from 80 to 100 lb. It became necessary to build this pressure up from 120 to 125 lb. during fire-drafts, due to inadequate feeders and supply mains to the distribution system. The unprecedented growth of the City of Atlanta and its suburban area, with rapidly increasing demands, emphasizes the necessity of a prompt survey of the distribution system and an analysis of flows, pressures, and drafts to determine the reinforcement necessary.

Cost of the Work

The following figures indicating the cost of the major items of the work completed, authorized, and contemplated, may be of interest:

Estimated cost, impounding dam, intake, etc.	$2 500 000
Mixing chamber and chemical house	176 000
48-in. raw water main and connections, including gate-house at reservoirs, aqueduct, tunnel, etc.	682 000
Filter plant, reservoirs and connections	699 000
Three 30 000 000-gal. turbo-centrifugal pumps erected (not including foundations)	192 000
Pumping station improvements, including steam improvements, and pump foundations, connections, cranes, etc.	300 000
Equipping thirty-six 500 000 gal. per day horizontal type filters, with loss-of-head gauges, rate controllers, and filtered water wash line with controller	42 000

General

The entire work has been under the general direction of W. Zode Smith, General Manager of the Atlanta Water-Works.

The 48-in. raw water main and connections, all suction and discharge headers, pump foundations, connections and exterior piping at the filter plant, were constructed and installed by the forces of the Water-Works Department with William M. Rapp, Superintendent of Construction, in charge. This work has been carried on efficiently and expeditiously, and well within estimates, and at a considerable saving over competitive bids.

The writer, acting as Consulting and Designing Engineer for the City of Atlanta, desires to give full credit and honor to his able corps of designers, resident engineers, and assistants, who have served so conscientiously and efficiently in the preparation of plans and the supervision of construction, including Frank J. Keis, M. Am. Soc. C. E., M. T. Singleton, M. Am. Soc. C. E., and Herman F. Wiedeman, Assoc. M. Am. Soc. C. E.; and Messrs. T. M. Sullivan, McDonald Lawrence, Lowell Cady, S. E. Arnold, and others. Mr. Wiedeman was Resident Engineer on the filter plant and clear water reservoir and during the period of "tuning up". Mr. J. N. Eley has co-operated with the writer in all mechanical and electrical matters, and supervised all duty and efficiency tests on the pumps and steam equipment.

DISCUSSION

J. N. CHESTER,* M. AM. SOC. C. E.—The definition of engineering has been stated as "the ability to adapt the forces of Nature to the uses of man", and to that might be added the provisions as well as the forces of Nature. As indicated in the paper, Atlanta has been especially favored with a remarkable source of water supply. The water is slightly contaminated, red with generous proportions of aluminum alkalinity, and the minimum run-off to date has been sufficient for the city, but, at times, the shortage has been acute. This, however, is not alarming considering that there are bountiful storage possibilities above and near the intake, and that in these storage possibilities there also appear to be power possibilities which may some day be developed to avoid the burning of coal for pumping.

With regard to early filtration plants, the Hyatt plant represents more nearly the early stage of the art than any the speaker has seen. There are a great many of these older plants still in operation, but most of them have been shorn of some of the elements of the early development and are operating much as the horizontal filters of the Atlanta plant; but the Hyatt plant shows how filtration was first conducted. At least one unit of that plant should be preserved so that engineers may be able to hearken back to where they started and demonstrate, in a measure at least, that the original filtration plants can produce as good an effluent as the modern ones with the actual process that was used in the original filter.

Every engineer who designs a new filter plant incorporates something that is not common to others. The outstanding features of the filter plant at Atlanta appear to be the single gallery and the open gallery as found to-day in few filter plants. The over-all filter house would come next, although that has been used in Cincinnati, Ohio, St. Louis, Mo., and Minneapolis, Minn., the last being the oldest of any material capacity. The extreme climate at Minneapolis was probably a strong argument for this type. In a southern climate, there are many features that can be adapted and incorporated that would not always be successful in the more severe northern climate. One of these is the concrete wash tank.

The speaker's early experience convinced him that the inherent principle of filtration was the balancing of the water between the coagulating basins and the filter tubs to produce an unrestricted slow flow from basins to filters and thus preserve the floc already formed. This question has been discussed with the officials of the City of Norfolk, Va., for whom the speaker has recently done some work. There the water is pumped from the coagulating basin by centrifugal pump to the filters and the officials are insistent that that does not prevent good filtration. When a new filtration plant was built, however, that feature was not incorporated in it.

The speaker has never before seen any plant in which the indicator on the wash line was calibrated to indicate the inches of rise of wash water in the

* (The J. N. Chester Engrs.), Pittsburgh, Pa.

tub. This feature is to be commended highly as it shows the extent of the rise, and, consequently, the rate of washing.

One feature of the pumping station that impressed the speaker was the use of centrifugal pumps on direct pressure where there must be at least a variation of 50% in demand. A basic principle of that type of pump is that they are most economical when discharging against a fixed head. If the demand is not equal to the capacity of the pump, it must increase the head and, therefore, affect the economy. For this reason it will be more interesting to learn what the operating results of this plant prove to be, as compared with others, than what test duty these pumps produce, because when the machine is being tested it must be operated under the conditions on which the guaranty is made, regardless of the subsequent operating conditions. No manufacturer could compete on anything except plainly stipulated conditions. That, therefore, is a feature of test conditions to which engineers have to defer and await the results after a number of years of service.

Nisbet Wingfield,* M. Am. Soc. C. E.—The water for the supply at Atlanta is taken from the Chattahoochee River (about 7 miles from the center of the city) and pumped to two raw water reservoirs in the city; from these it flows by gravity through the coagulating basin and filters to a clear water basin, and thence to the pumps supplying the city. This basin, called the Hemphill Station, is 100 ft. below the high points in the distribution system. The pressure on the mains is maintained by the pumps at all times, there being no service reservoir. The lift from river to raw water reservoirs is 227 ft. From the Hemphill Station it is 100 ft. plus the pressure on mains, making a total lift of 185 ft. for domestic pressure and 285 ft. for fire pressure.

Many of the problems that have confronted the municipal authorities in maintaining an adequate water supply in Atlanta are similar to those arising in every growing community, but the growth of Atlanta, both numerically and industrially, has been excessively rapid in the last fifteen years, so that the situation at times has been acute. This applies to schools, transportation, water-works, and every other public service, and means that an extra burden has been put on those entrusted with these public utilities. How well they have stood the test has been indicated by the fact that no serious interruptions of the service have occurred, although at times the situation must have been very trying.

For years Atlanta has been outgrowing its income, that is, the needs of the public service institutions have been greater than the funds available. An effort to catch up at least partly in the Water Supply Department has been made by a recent bond issue of approximately $3 000 000. As explained in the paper, this was not sufficient to carry out the plans in their entirety, but has been sufficient to put the pumping, filtration, and storage capacities on a good basis, but the distribution system is not adequate by any means. New centers of distribution are being formed so frequently, on account of the building up of certain sections, that an adjustment in the pipe system is

* Cons., Municipal and Hydr. Engr., Augusta, Ga.

needed to meet these changed conditions, and additional funds should be provided for this purpose with as little delay as practical.

The City of Atlanta occupies the highest ground for miles, in either direction, hence there is no opportunity for a service reservoir sufficiently elevated to supply the city by gravity. Additional fire pressure in the mains (100 ft.) is not intended to furnish hydrant fire streams, its object being to force sufficient water through the small mains for use of fire pumping engines—this in lieu of larger street mains, which otherwise would be necessary.

The direct pumping and the varying pressure render it necessary to equip and maintain larger pumping units than would be necessary under ordinary conditions of service. The average consumption per day at this time ranges from 26 000 000 to 30 000 000 gal., but during the 24-hour period the rate of pumping varies from 17 000 000 to 50 000 000 gal. per day, and the pressure against which the pumps must work varies from 80 to 125 lb.

This varying condition of service does not apply, of course, from the river station to the raw water reservoir, where a constant rate of pumping may be maintained against a uniform pressure, the difference in elevation between the surface water in the suction well at the river station and the raw water reservoir being 227 ft. The difficulties which have been encountered heretofore in the operation of this station have been due to the fact that water is taken directly from the Chattahoochee River through a single conduit to a suction well of small capacity, and to the further fact that neither the 30-in. nor the 36-in. raw water discharge pipes had sufficient capacity to take care of this service alone, and an interruption of the service in either necessitated raising the pressure on the pumps above that for which they were designed, in order to overcome friction.

The trouble with the intake pipe is due to the tremendous variation in the flow of the river—the low flow being less than 400 cu. ft. per sec., whereas the flood flow is more than 100 000 cu. ft. per sec. During low flow the intake is not entirely submerged and the quantity of inflowing water is uncertain, while during periods of high water constant attention is necessary to prevent flooding through the intake well while still maintaining the proper flow to the pumps. When the impounding reservoir is constructed, as recommended in the paper, this trouble will be eliminated.

The present pumping capacity of the Chattahoochee River Station is 106 000 000 gal., and the three discharge mains have been cross-connected in several places, so that as soon as the intake from the river is reconstructed there should be no difficulty in delivering the required quantity of water into the raw water reservoirs.

At the Hemphill Station the pumping capacity is 95 000 000 gal. per day, with a clear water basin of 10 000 000 gal. capacity from which to pump, and filters of 42 000 000 gal. capacity constantly feeding it, so that to handle this plant properly all that is now necessary is to increase the sizes of the street mains, thus reducing the pressure to overcome friction.

Probably the most interesting feature of the Atlanta Water-Works is the filtration plant, which, to say the least, is unique in that the gravity filters

and pressure filters are operated in conjunction, this arrangement being made in order not to scrap the old pressure filter plant of 21 000 000 gal. capacity, which had proved through long years of excellent service that it had a right to live. Any one who has been actually in charge of the operation of a filter plant with a highly turbid raw water will appreciate the difficulty of suitably treating 30 000 000 gal. per day, having a peak draft of 50 000 000 gal. per day, with a filter capacity of 21 000 000 gal., and a clear water basin capacity of 2 000 000 gal. This was the condition of Atlanta before the construction of the filtration plant just completed.

The waters of the Chattahoochee River are, in all important particulars, similar to other rivers in the South Atlantic States, that is, the water is of good chemical quality, with few harmful bacteria, but carrying in suspension at all times large quantities of clay and silt of reddish-yellow color, varying in quantity with the different seasons. The principal work for the filtration plant, therefore, is to remove this color.

Under normal conditions the total suspended solids are approximately 43 grains per gal. From tests made by the speaker it was found that in 72 hours, with the water quiet, there was a precipitation of 32 grains, leaving 11 grains which would not precipitate. This residue of 11 grains is the exceedingly fine particles which give color to the water, so that if a settling basin of sufficient capacity is provided, the output of the filters will be largely increased. With water constantly passing through the basin the body is more or less disturbed, and precipitation will be slower. For this reason an additional length of time beyond 72 hours should be given.

The capacity of the raw water reservoirs in Atlanta is 393 000 000 gal. These reservoirs, acting as settling basins, gave sufficient time for settling, thus furnishing to the filters a water comparatively easy to treat, and making the 21 000 000 gal. capacity filter plant just about ample with a rate of filtration of 3 gal. per min. per sq. ft. At times, however, the filtered water had too much color. Many of the suspended particles giving the color are so minute that they will not be caught on the filter bed, unless the rate is extremely slow. Discolored filter water, therefore, means that the rate of filtration has been too rapid. This has now been cured, and there should be no further trouble until the rate of consumption is materially increased.

The old filter plant is interesting also, from the fact that it was the first mechanical filtration plant constructed to treat the whole supply of a municipality. The original plant consisted of twelve Hyatt filters, with combined capacities of 3 000 000 gal. in 24 hours. Previous to this time smaller units had been installed in several places in the East, but Atlanta has the distinction of being the first city supplied through a mechanical filtration plant. These filters had two chambers, an upper and a lower. The filtering was done in the lower chamber, and when it was necessary to wash the filter bed, the sand was lifted by hydraulic apparatus from the lower chamber to the upper chamber and washed, and then returned to the lower chamber. The operation of this plant was successful, due to the fact that the water was taken from a large impounding reservoir, where previous settlement had taken place.

Several years later (1887-90), in order to lessen the original cost of filtration works, attempts were made by other manufacturers to filter public supplies without previous sedimentation, the water being drawn direct from a turbid stream and forced under pressure through filters located on the discharge pipe. Notable examples of this were: New Orleans, La., taking water from the Mississippi River, Little Rock, Ark., with water from the Arkansas River, and Chattanooga, Tenn., taking water from the Tennessee River. In each case the attempt was unsuccessful, due to the fact that silt and other suspended matter quickly formed a mat on top of the filter bed, with the result that the more pressure applied from the pumps, the denser the mat became, almost entirely stopping the flow. In several instances the filter cases were torn open by pump pressure.

These plants and many other smaller ones of which the speaker has personal knowledge, where the filter installations were similar, were later used as gravity plants, by the construction of settling and clear water basins, so placed that the pressure filter cases and pipe systems could be used without alteration, the water passing through the beds by gravity instead of under pressure. In all cases the change from pressure to gravity filters, with previous sedimentation, had the desired effect and potable water was obtained without trouble.

When the source of water supply for Atlanta was changed from South River to the Chattahoochee River, and the existing raw water reservoirs and pumping plants constructed, the twelve vertical Hyatt filters were moved from South River and set up at their present location, between the raw water reservoir and the Hemphill Pumping Station, and a small clear water basin constructed, the water passing by gravity from the raw water basin through the filters to the clear water basin, with a fall from the raw water reservoir to the clear water basin of 40 ft.

The capacity of the filtration plant was increased by the addition of twelve New York horizontal filters with a rated capacity of 500 000 gal. each, giving a total capacity of 9 000 000 gal. During the past twenty years this capacity has been increased to a total of 21 000 000 gal. This plant worked satisfactorily until the consumption exceeded the plant capacity. In connection with the new plant just completed, it will no doubt continue to give excellent service, provided the raw water is given not less than 72 hours of sedimentation, and the rate of filtration does not exceed 2 gal. per min. per sq. ft. of filter bed.

HIGH SPECIFIC SPEED TURBINES

By George A. Orrok,* M. Am. Soc. C. E.

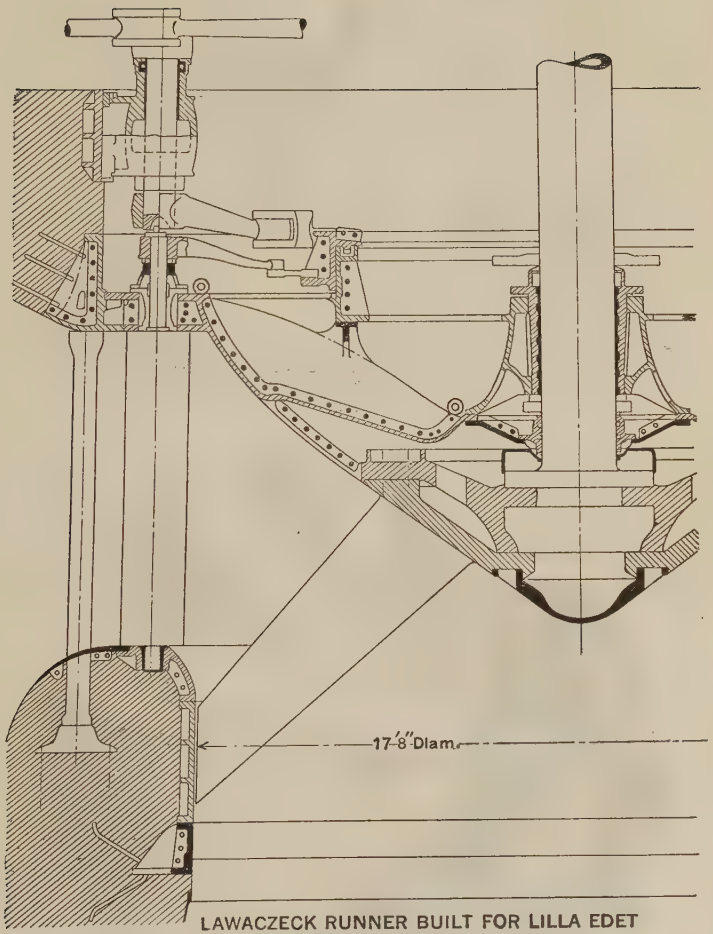
Among the many things of interest seen and heard at the World Power Conference (London, 1924), none perhaps was more striking than the variety of methods proposed and tried for the solution of the important problem of high specific speed turbines. From talks with experimenters and visits to European testing laboratories, from the papers on these laboratories and their work presented to the Conference, and from current literature in many languages, the speaker believes that although the subject is not new and is well known in America, yet the many excellent examples of good design and construction at present under way in Europe should be better known to members.

Among the larger plants, the Chancy-Pougny installation of five wheels (7 600 h.p.), on the Rhone, below Geneva, Switzerland, is most interesting. The turbines are 18 ft. 0 in. in diameter, under 26.7-ft. head, with a characteristic speed of about 120, just a trifle larger than those at Keokuk, Iowa. The wheels are a modified Francis type, retaining the outer rim, and were built by the Des Charmilles Company, of Geneva; they are guaranteed for an efficiency of more than 90% at the best gate-opening.

In comparison, the Lawaczeck wheels for Lilla-Edet, Sweden (Fig. 1), are 19 ft. 8 in. in diameter without the outer rim, and have a characteristic speed of 136; the head is 21.3 ft. instead of 26.7 ft., the power is 10 000 h.p., and the water used is 5 200 cu. ft. per sec., instead of 3 250 cu. ft. per sec. A similar wheel, 9 ft. 6 in. in diameter, at the Viereth plant in Germany gives 2 000 h.p., with a 17.4-ft. head and a speed of 93 (Figs. 2 and 3). This latter wheel was made by the Neumeyer Company, of Munich, Germany, and showed test results considerably better than runners of the Francis type for the same head and speed. About sixty runners of this type have been tested during the last year (1924).

The Lilla-Edet plant has two of the 19 ft. 8-in. Lawaczeck runners installed, and the third unit is a propeller runner with adjustable blades of the Kaplan type. This third runner has about the same diameter and water capacity as the others, but the blades are adjustable, giving much better efficiency at low gate-openings. The Swedish Government has installed a testing laboratory at Lilla Edet and models of both wheels, 1 m. in size, were given an exhaustive test before the contracts were signed. Dr. D. Thoma, Professor of Hydraulic Engineering, Technische Hochschule, Munich, Germany, has stated that the form of the Lawaczeck runners is a mathematical surface with three parameters and that the test efficiencies may be related to the equations of the surface. He further states that this method of analysis will prove fruitful without restriction to any special theory of turbine design.

* Cons. Engr., New York, N. Y.



LAWACZECK RUNNER BUILT FOR LILLA EDET

FIG. 1.

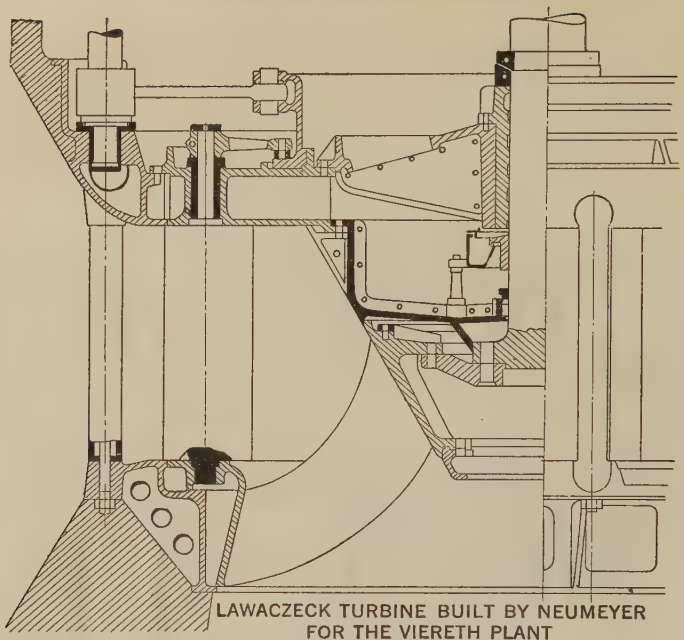


FIG. 2.

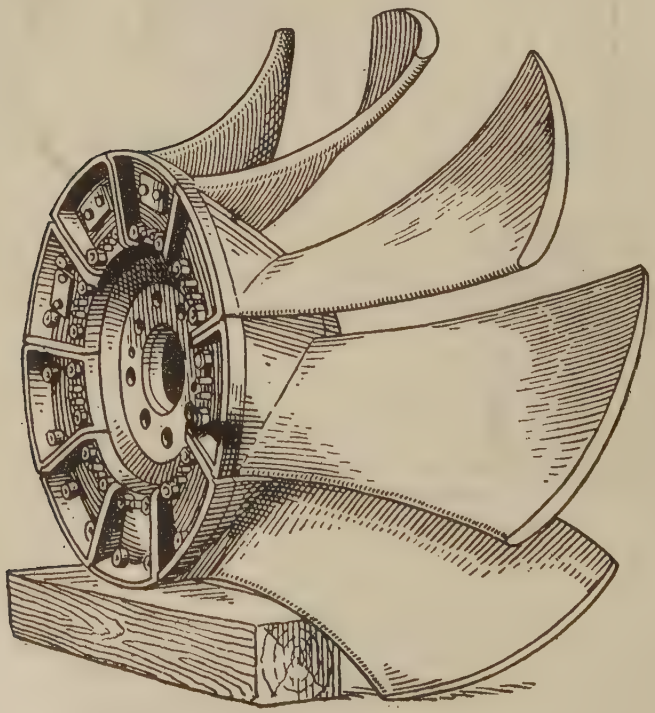

FIG. 3.—LAWACZECK RUNNER (9 FT. 6 IN. IN DIAMETER) FOR THE VIERETH PLANT.

The Kaplan runner at Lilla Edet is 19 ft. 0 in. in diameter and gives 11 200 h.p. It has four blades, adjustable while running. The design included a special draft-tube for each type of wheel. Actually, however, the second Lawaczeck runner was installed in a draft-tube designed for the Kaplan runner. The performance of the wheels at Lilla Edet is shown in Fig. 4.

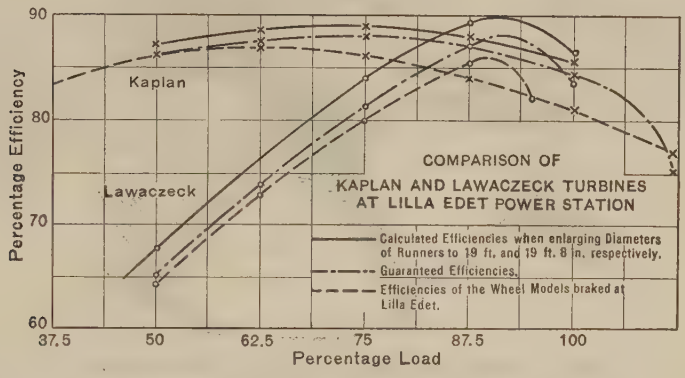

FIG. 4.

J. M. Voith and Company, of Heidenheim, Germany, has also manufactured a number of Kaplan runners, the first having been installed at Siebenbrunn, Austria (Fig. 6). This wheel is 6 ft. 3 in. in diameter, with 20.3-ft. head, and develops 400 h.p. at 250 rev. per min. The specific speed is about 212. There is a similar wheel, 5 ft. 1 in. in diameter, with a speed of 250 rev. per min., under a 13.75-ft. head, at Gävle, Sweden; apparently, a considerable number of these wheels have been made by other manufacturers.

The Voith Company has also been manufacturing wheels of the Kaplan type with fixed vanes. The installation at Kachlet, Germany, on the Danube, is quite interesting. Here, the wheels are 15 ft. 1 in. in diameter (Fig. 5), under a 25.1-ft. head, for 7 450 h.p., giving a specific speed of about 115. The runner has six blades covering nearly the entire area, whereas the four-bladed Kaplan designs do not cover much more than one-quarter of the projected area. Escher, Wyss and Company (Zurich, Switzerland), is also making a propeller turbine for which tests show good efficiency. In Fig. 7 is shown a six-bladed model; Fig. 9 shows performance curves of a four-bladed model. The tests of an interesting two-bladed helical runner (Figs. 8 and 10), made by Theo. Bell and Company (Kriens, Switzerland), have been published by Dr. F. Prazil, in Zurich. A turbine of this type for which the performance curve is shown in Fig. 10, is situated at the Matte Central Station in Berne, Switzerland. Dr. Hahn has given a table of test efficiencies of runners of this type collected from a number of European sources. Statistics of some of these high-speed European plants are given in Table 1 and comparative performances in Fig. 11.

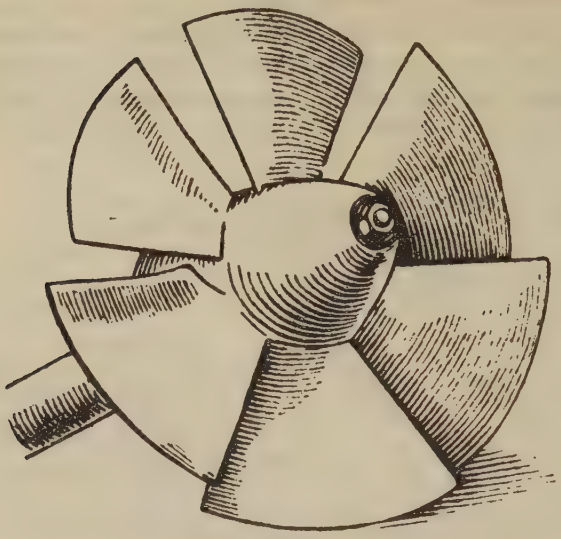

FIG. 5.—VOITH RUNNER (15 FT. 1 IN. IN DIAMETER) FOR THE KACHLET PLANT.

In his paper* before the World Power Conference, Dr. Thoma emphasizes the fact that the tests on small-sized, geometrically similar models give reliable figures for large-sized operations and that in the few cases of divergence noted a lack of geometrical similarity has been proven. He also states that the Camerer correction formula for efficiency has been found to be fairly correct. He gives a list of thirteen hydraulic testing laboratories actually running in Germany alone.

this subject. In conversation, he stated that this problem in the high-speed runner can be solved. Meanwhile, reports as to the performance and life of these large sized and particularly high-speed runners will be awaited with avidity. The speaker believes the high-speed runner has come to stay and that present difficulties with this type will be overcome, as with the older and better understood designs.

THE PROPELLER TYPE TURBINE

By Lewis F. Moody,* Esq.

To any one who has followed hydraulic power engineering it must seem surprising that a machine so highly developed as was the hydraulic turbine ten or fifteen years ago, should have suddenly entered a period of radical changes and encountered transformations in many of its essentials. The fact remains, however, that although practice in turbine design had become almost standardized in the period just prior to the World War, the development of this art has taken on new life and has already been revolutionized in many aspects.

The most striking changes have been those in runner and draft-tube design, resulting in a remarkable increase in the specific speeds. This paper is directed particularly to one form of high-speed turbine and to the description of a number of typical installations, representing some of the most recent developments in this field. Before describing particular installations, however, a few general relations will be discussed leading to some of the reasons which account for the adoption of the propeller type of runner and which explain at least in part the logic of its development.

The first point discussed is not directly pertinent, but is of some interest in itself, namely, the relation between size of turbine and efficiency; the second point then follows—the relation between type or form of turbine and its efficiency and specific speed. The results of several actual tests of models of the propeller type and of large-sized installations will then be presented.

Variation of Efficiency with Size of Turbine

In order to compare results secured on different sizes of models with full-sized turbines, the writer has believed it advisable to take up the question of the effect of size on turbine performance in a series of homologous turbines. In recent years calculations for this purpose have usually been based on the Camerer formula, of the form:

$$e' = 1 - (1 - e)\frac{0.12 + \sqrt{\frac{0.015}{\left(\frac{f_2}{U_2 D}\right) D'}}}{0.12 + \sqrt{\frac{0.015}{\left(\frac{f_2}{U_2 D}\right) D}}}$$

in which, e equals the efficiency of one turbine, e' that of another turbine; D and D' are their diameters; and $\frac{f_2}{U_2 D}$ is the ratio of the outflow area, f_2, of the

* Cons. Engr., I. P. Morris Dept., The William Cramp & Sons Ship & Engine Building Co., Philadelphia, Pa.

runner buckets to the product of the wetted perimeter and the runner diameter; that is, the ratio of the hydraulic radius of the runner bucket exit area to the runner diameter.

Although the Camerer formula has been found to be in fairly good agreement with actual results of tests, it is not altogether satisfactory for the following reasons:

1.—It involves the calculation of the hydraulic radius of the water passages through the turbine and cannot be accurately applied unless the design of a particular turbine is available. It is complicated in form and involves a number of constants or coefficients which can only be accurately determined by applying it to a number of installations of similar general character to any case under consideration. In determining the hydraulic radius to be applied in the formula, it would be necessary to arrive at some average value which would fairly represent the entire course of the water through the turbine, a matter of considerable complication even when the design is fully known. Camerer avoids this complication by using the minimum section which usually occurs at the outlet orifice of the runner buckets. Although the formula has been generally used with this assumption, it no longer remains entirely rational.

2.—The formula is also derived from the assumption that all the losses through a turbine are due to surface resistance or so-called "pipe friction", and discards the consideration, which was recognized by Dr. Camerer, that a part of the losses in a turbine is due to eddies, impact, and velocity head rejected at final discharge. The complicated form of the Camerer expression is due to the fact that it is based on Dr. Biel's formula for pipe friction which is an expression involving the sum of three terms.

Considering the fact that the losses in a turbine are dependent on many factors and involve many complications and that in comparing efficiencies only approximate results at best can be expected, the writer believes that a simple form of expression involving only the leading variables and giving a simple dimensional relation without including the details of design, can be used with a gain both in convenience of application and in accuracy. For this purpose the writer proposes in place of the Biel formula for pipe friction or other complex form of expression, such as the Kutter formula for channels, the use of an exponential formula, and for this purpose suggests either the recent Forcheimer formula:

$$V = k\, R^{0.7}\, J^{0.5}$$

in which,

V = velocity;
R = hydraulic radius; and
J = slope of hydraulic gradient;

which is equivalent to:

$$J = \frac{V^2}{k^2\, R^{1.4}}$$

or the still more recent Strickler formula:*

$$J = \frac{V^2}{K^2 R^{\frac{4}{3}}}.$$

The Strickler formula is based on rational grounds and has been shown to be in close agreement with a large range of actual measurements. If λ represents the proportional loss of head in a given turbine expressed as a fraction of the total head on the turbine, then $\lambda = 1 - e$, in which e is the turbine efficiency.

If $\lambda = 1 - e$ is the proportional loss of head in one runner, say, a small model, assume that a certain fraction, a, of this loss, that is, $a\,(1 - e)$, remains unchanged as the runner is increased (homologously) in size; while the remaining portion, $(1 - a)\,(1 - e)$, is due to surface friction, so that the proportional loss in another, say, a larger, runner, will be:

$$\lambda' = 1 - e' = a\,(1 - e) + \lambda'_f$$

Now the surface friction in any channel may be calculated by the exponential formula:

$$h_f = f \frac{L}{R^x} V^m$$

in which, except for very smooth pipes of small diameter, m may be taken as closely equal to 2, a value corresponding to cast-iron pipes, and x may be taken between 1.4 (Forcheimer) and 1.167 (Hazen and Williams), or as $1\frac{1}{3}$ (Strickler) (also proposed by Manning, 1890).

Calling $x = 1 + p$, in which $p = \frac{1}{3}$, if the Strickler value is used,

$$h_f = f \frac{L}{R} \frac{V^2}{R^p}$$

Expressed as a fraction of the total head on the turbine,

$$\lambda_f = \frac{h_f}{H} = f \frac{L}{R} \frac{V^2}{R^p H}$$

In homologous runners of all sizes, under any head, when operating at equal gate and corresponding speeds, V^2 varies directly as the head, H, so that $\frac{V^2}{H}$ = a constant; and in all homologous runners, $\frac{L}{R}$ = a constant; and as R is proportional to D, the runner diameter,

$$\lambda_f = \frac{k}{D^p} = (1 - a)\,(1 - e);$$

and

$$\lambda'_f = \frac{k}{D'^p}.$$

* "Beitrage zur Frage der Geschwindigkeitsformel und der Rauhigkeitszahlen für Strome, Kanale und geschlossene Leitungen," by A. Strickler, *Schweizerische Bauzeitung*, June 7, 1924, p. 265.

Hence, putting:

$$k = (1 - a)\ (1 - e)\ D^P,$$

we have:

$$\lambda' = (1 - e') = a\,(1 - e) + (1 - a)\ (1 - e)\ \frac{D^P}{D'^P}$$

or,

$$\frac{1 - e'}{1 - e} = a + (1 - a)\left(\frac{D}{D'}\right)^P$$

From the application of this formula to a number of actual comparative tests, it was found that if P is taken as $\frac{1}{3}$, then a, the unvarying portion of the loss, is a comparatively small fraction, approximately $\frac{1}{4}$; and it is also found that the whole loss can be closely approximated for usual values by substituting for $a + (1 - a)\left(\frac{D}{D'}\right)^P$, the simpler expression, $\left(\frac{D}{D'}\right)^n$, in which a slight change in P to n closely compensates for the dropping of the constant term. Moreover, there is basis for believing that a varies with size of runner; in a small runner the vanes are relatively thicker, less sharply pointed, and less accurately formed, and have a greater eddy loss at their discharge edges and elsewhere. Hence, an expression of the form:

$$\frac{1 - e'}{1 - e} = \left(\frac{D}{D'}\right)^n$$

should be sufficient for all practical purposes in computing the effect of size on efficiency; and an application to a number of actual tests shows this to be true, with n varying but little from the value of $\frac{1}{4}$.

Therefore, the following formula may be used:

$$e' = 1 - (1 - e)\left(\frac{D}{D'}\right)^n$$

or,

$$e' = 1 - (1 - e)\left(\frac{D}{D'}\right)^{\frac{1}{4}}$$

Effect of Change of Form of Turbine on Efficiency and Speed

The preceding discussion applies to geometrically similar turbines. Consider, next, the effect of change of form or type of turbine. The particular change which it is desired to consider is that from a so-called Francis turbine to a turbine of the propeller type. This change in type involves the following principal alterations: (*a*) The elimination of the runner band or shroud ring, allowing the blades to rotate within a stationary wall; (*b*) the introduction of a large transition space between guide-vanes and runner, in which the water follows a free path and turns from a radial to a partly or completely axial direction; (*c*) the reduction of blade surface so that the blades either overlap each other only slightly or fail to overlap at all and leave clear openings between them; (*d*) a reduction in the number of blades; and (*e*) the use of draft-tubes symmetrical about the turbine axis and capable

of efficiently converting into useful head the velocity head of both the meridian and tangential components of the runner discharge velocity, thus permitting both components to be made relatively large.

The effect of each of these changes is to allow the runner to be operated at a higher speed under a given head, by permitting higher relative velocities to be used and a more inclined direction of the absolute velocity of runner discharge.

The reason for eliminating the band or shroud is simple. With the runner speeds and diameters used, the relative velocity of the water in contact with a moving band would be considerably greater than its absolute velocity along the surface of the stationary wall, so that there is less surface resistance on the inner surface of the band when it is stationary than when it rotates; and by replacing the rotating band by a stationary wall, all the frictional resistance of its outer surface is eliminated.

The effect of the transition space is to reduce the relative velocity between the water and the blades at all sections except at the blade tips. If this space is too much enlarged, however, or if the entrance edges of the blades are carried too near the axis, the relative velocity near the hub begins to increase again, the water at that point then tending to rotate faster than the runner, and, in addition, the surface friction due to the long absolute path along the stationary head cover partly discounts the decrease in blade friction. This consideration is one which has led to the writer's diagonal type of runner, intermediate between a radial and a purely axial flow runner. In a similar way, an undue reduction in blade surface while decreasing the surface resistance, if carried too far results in imperfect guidance of the flow and permits other losses which more than offset the gain. It has been found both from theory and experience that unduly small blade area greatly impairs the stability of operation, giving rise to surging, unstable flow, and loss of efficiency, and materially reduces the field of application of turbines of the propeller type in which it is found.

The effect of reducing the number of blades can be readily investigated along the lines of the analysis given previously for homologous runners. Assume a series of runners in which the same ratio of total blade area to disk area is used, but in some of which there are many blades with short and narrow passages between them and in others of which there are a few blades with long and wide passages, the blade sections being geometrically similar in all and having the same ratio of length to width of passages. The runners being unshrouded, the wetted perimeter of a runner channel may be taken as approximately equal to twice the blade length from hub to band plus the hub surface; and if the hub surface is neglected and offset approximately by taking the blade length as if it extended to the axis, the wetted perimeter can be called $2\,r$, in which, r is the tip radius of the blades, measured in a conical surface. The area of one runner passage is:

$$\frac{r \times 2\,\pi \frac{r}{2} \sin \beta}{z}$$

in which, β is the blade inclination and z is the number of blades. Hence, the hydraulic radius of a runner passage is:

$$\frac{\pi r^2 \sin \beta}{2 z r} = \frac{\pi r \sin \beta}{2 z}$$

With the same line of reasoning, the proportion of the total head on a turbine lost in blade friction will vary inversely as the hydraulic radius raised to the nth power, or using the Strickler value of $n = \frac{1}{3}$, the ratio of blade friction losses in two runners can be expressed as:

$$\frac{\lambda'_b}{\lambda_b} = \left(\frac{\frac{\pi r \sin \beta}{2 z}}{\frac{\pi r' \sin \beta}{2 z'}} \right)^n = \left(\frac{r}{r'} \frac{z'}{z} \right)^{\frac{1}{3}}$$

This relation shows that in such a series of runners as described the blade friction will vary directly as the cube root of the number of blades, and inversely as the cube root of the radius. For example, comparing a 16-vane runner with a 4-vane runner, the latter will have $\left(\frac{4}{16}\right)^{\frac{1}{3}} = 0.63$, or 63% of the blade friction loss of the first, or a reduction of 37 per cent. It must be kept in mind that this does not mean keeping the blades the same in size as their number is reduced, but enlarging them to keep the total blade area the same. Although a very small number of blades will be advantageous in reducing this particular loss, there are, of course, certain disadvantages in carrying this feature too far, such as the increase in axial length of the runner hub and blades, with resulting increase in weight of runner and the distance of its center of gravity from the bearing, increase in length of the surrounding ring, and greater loss in friction against the ring.

In considering the last factor, the change in form of draft-tube, no attempt at a general analysis of the effect of form of draft-tube on the performance of turbines of the propeller type will be given in this paper, as the subject has been rather exhaustively treated in other papers; it may be pertinent to point out, however, that one of the objects of recent studies on the draft-tube feature of these turbines has been the reduction in over-all dimensions without impairing the performance. To give an idea of what has been accomplished in this direction there are shown in Fig. 12 a model of the propeller type tested with a spreading draft-tube of large dimensions, in comparison with a recent design of a spreading spiral tube tested with the same model; and, in Fig. 13, the performance curves are compared.

Typical Test Results on Propeller Type Models

In Figs. 14 and 15 curves of efficiency plotted against specific speed are shown for two turbines of the propeller type of the form developed by the writer from Holyoke tests. Each of the individual curves on these sheets represents a particular gate-opening; the envelope shows the efficiency obtainable at various specific speeds.

Some Typical Installations

Having discussed from a somewhat theoretical standpoint, a few of the factors affecting the design of these turbines, brief descriptions of a few recent installations will now be given to conclude this paper.

Fig. 16 shows one of the four 30 000-h.p. runners at the La Gabelle plant of the St. Maurice Power Company. These units have already been described in other papers, as have the similar 28 000-h.p. turbines of the Manitoba Power Company, Limited. It may be pointed out that the La Gabelle draft-tubes are closely similar to the spreading-spiral form shown in Fig. 12. The Manitoba units have been in operation under a wide range of heads—to more than 50 ft.—for about 2 years, and the La Gabelle units for nearly a year, under heads to more than 60 ft. It may be reported as a result of the experience with these units that the Manitoba runners have shown a slight tendency toward corrosion on the discharge edges of the blades, due perhaps to the abnormal operating heads, but the effect is local and not serious. The La Gabelle runners are in perfect condition. In both plants the concrete just below the runner has been eroded, and this has been corrected by the addition of plate-steel liners at the top of the draft-tube, a practice which will be followed in future installations of the propeller type under the higher heads. In all the remaining installations to be described subsequently, there has been an entire absence of pitting or corrosion at any point; and in all these installations, including the Manitoba and La Gabelle units, the operation has been characterized by quietness, steadiness, and freedom from surging or vibration or other difficulties, and in every case the calculated power output has been exceeded by a reasonable margin.

Figs. 17, 18, and 19 show the 1 500-h.p. units at the Feeder Dam plant of the Moreau Manufacturing Corporation on the Hudson River, near Glens Falls, N. Y. There are five of these units with a rated capacity of 1 500 h.p. each, operating under a normal head of 15.5 ft. and a maximum head of 19 ft. The speed is 120 rev. per min., corresponding to a specific speed of 151.5 (672 metric). The design has been simplified as far as possible and the object has been to keep the cost of turbines as low as possible without sacrificing mechanical dependability or the hydraulic conditions of operation. On account of the low head available for this station, a minimum cost of the development is naturally of great importance. In this plant an outside operating mechanism has been dispensed with, the gates being operated from links connected directly to the vanes, by means of a vertical gate-shaft. The runners are of cast iron, the casing stay-vanes are separate castings set individually in the concrete, and no continuous "speed ring" is used. The draft-tube is a relatively short spreading tube with the barrel or spreading portion of plate steel. These units have been in actual operation for several months and tests of power output have shown excellent agreement with the predicted values.

Fig. 21 shows a sectional elevation of one of the 1 500-h.p. turbines for the Anson plant of the Great Northern Paper Company, near Madison, Me. Fig. 20 shows an interior view of the power-house. This plant has been in operation for about fourteen months. Fig. 22 shows the efficiency curve secured

in a test of one of the full-sized units under actual operating conditions. This test was made by C. M. Allen, M. Am. Soc. C. E., using his salt-velocity method of water measurement, the water being measured in an open flume constructed in the tail-race. There are five of these units of 1 500-h.p. capacity each, operating under a normal head of 20 ft., at a speed of 150 rev. per. min. This speed corresponds to a specific speed of 137 (610 metric). These turbines have integral stay-vane rings or speed rings, outside operating mechanism actuated by a vertical gate-shaft, and the runners are of cast iron. The draft-tubes are of the spreading type.

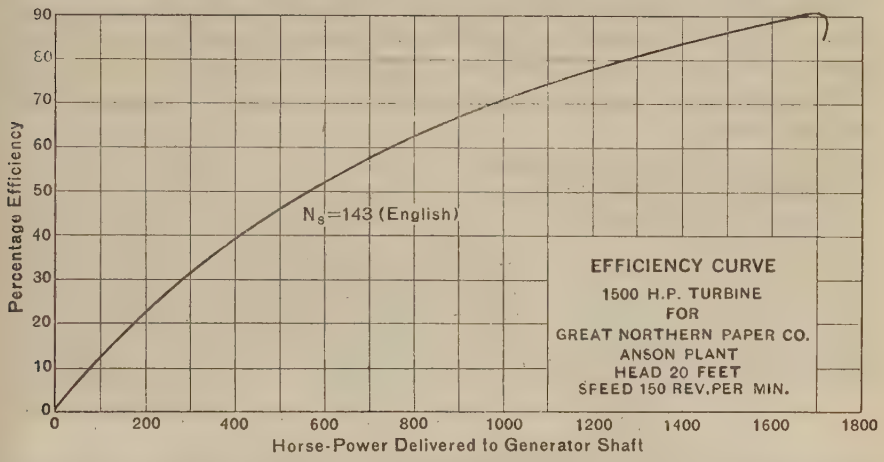

FIG. 22.

An installation very similar in design to the Feeder Dam and Anson plants is that of the Spruce Falls Company, Limited, at Kapuskasing, Ont., Canada. This plant was built by the Dominion Engineering Works, Limited, and involves a propeller type unit of 2 500 h.p., under a 30-ft. head, operating at a speed of 180 rev. per min. This corresponds to a specific speed of 128 (571 metric). Preliminary reports of a test made by Professor Allen indicate that the efficiency will probably be in excess of 90 per cent.

Other recent installations of the same type of turbine carried out in Canada are the following:

Two units for the Howard Smith Paper Company, of 350-h.p. capacity each, under a head of 8 ft. These have a speed of 99 rev. per min., corresponding to a specific speed of 134 (597.5 metric).

One unit for the Dryden Paper Company of 1 400-h.p. capacity, under a head of 29 ft., at a speed of 225 rev. per min., corresponding to a specific speed of 125 (556 metric).

These installations were built by the Dominion Engineering Works, Limited, of Montreal, Que., Canada, which also has under construction two turbines of 6 000-h.p. unit capacity for a head of 30 ft. normal, and 34 ft. maximum, for the Southern Canada Power Company. The draft-tubes are of the spreading type formed in concrete and will be provided with separate cast stay-vanes at the end of the spreading portion to carry the weight of the

superposed structure. Similar stay-vanes were used in the Manitoba and La Gabelle installations and in a large number of Francis turbine installations. These vanes have been found to be a valuable structural feature reducing the reinforcement in the power-house substructure which would otherwise have to carry the loads by beam action, and also proving useful during construction as they permit the earlier removal of forms. These turbines will have removable liner rings surrounding the runners; the runners will be of cast steel. The operating mechanism will be of the outside type. These units will operate at 138.5 rev. per min., or a specific speed of 153 (680 metric).

Among the recent installations in the United States may be mentioned a unit of 3 200-h.p. capacity for the Roanoke Rapids Power Company. This turbine operates under a head of 30 ft. at a speed of 163.6 rev. per min., or a specific speed of 131.5 (585 metric). This unit will also be equipped with cast-steel runner.

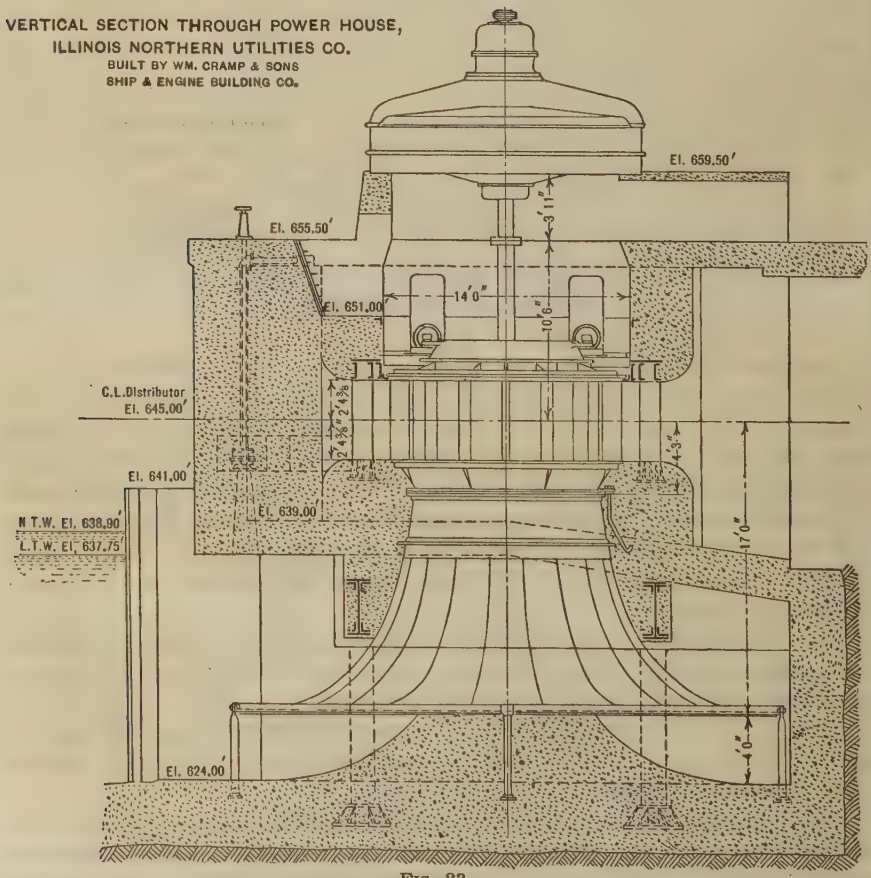

FIG. 23.

An installation of particular interest, the construction of which has recently been completed, is that of five units for the Illinois Northern Utilities Company, shown in section in Fig. 23. These turbines will have a unit capacity

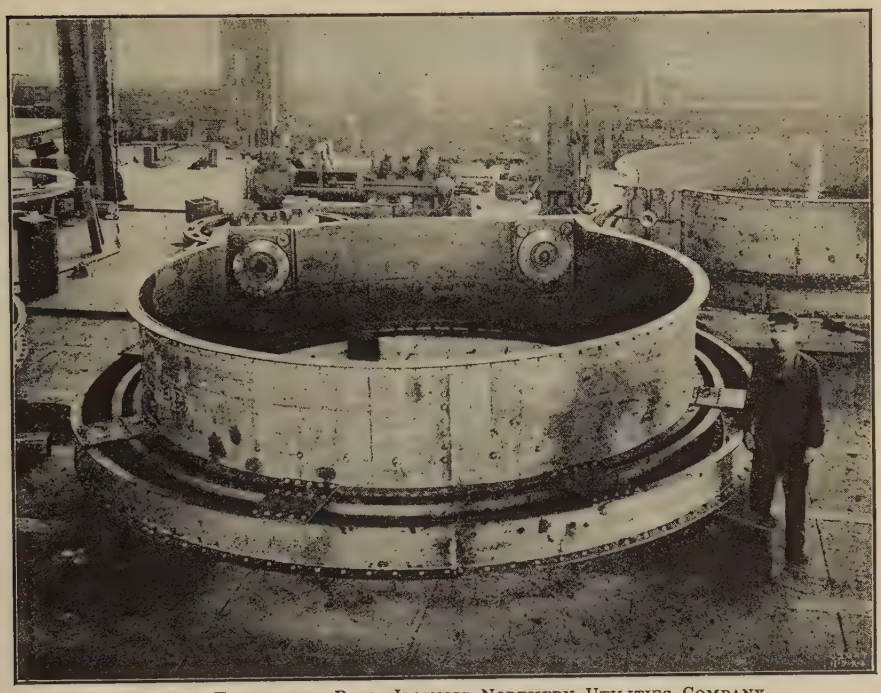

FIG. 24.—FOUNDATION RING, ILLINOIS NORTHERN UTILITIES COMPANY.

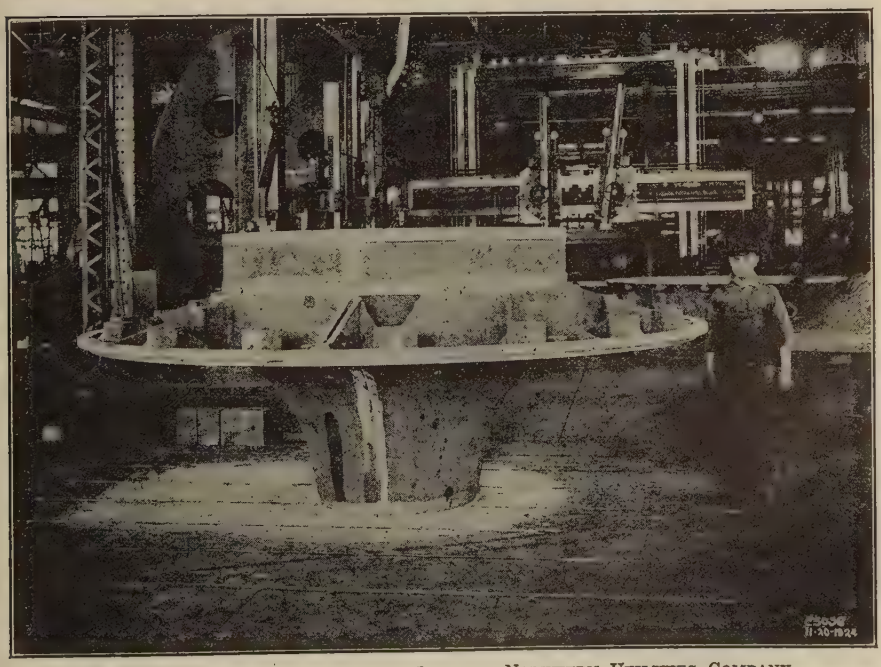

FIG. 25.—TURBINE HEAD COVER, ILLINOIS NORTHERN UTILITIES COMPANY.

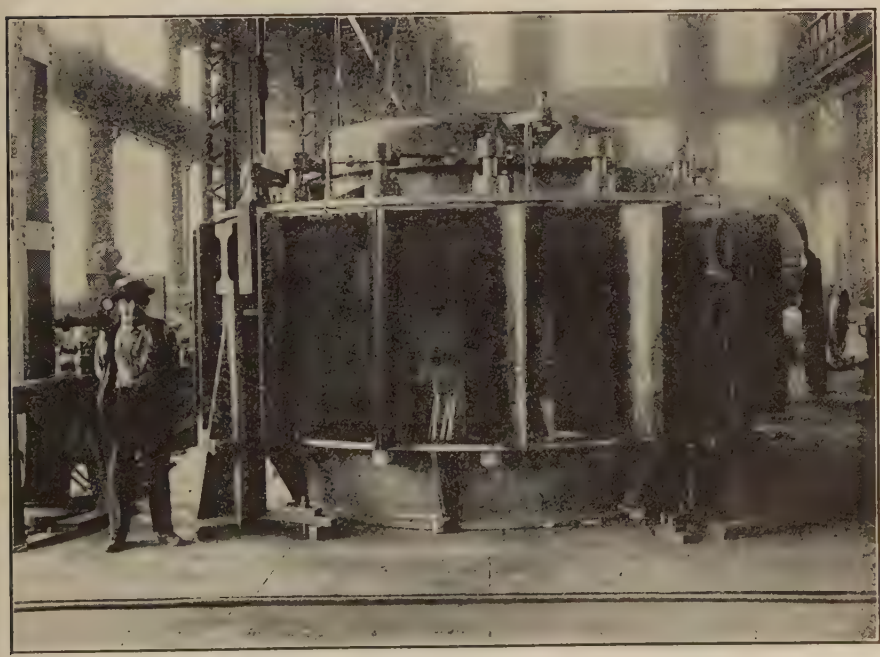

FIG. 27.—PARTIAL ASSEMBLY OF 800-H.P. TURBINE FOR ILLINOIS NORTHERN UTILITIES COMPANY.

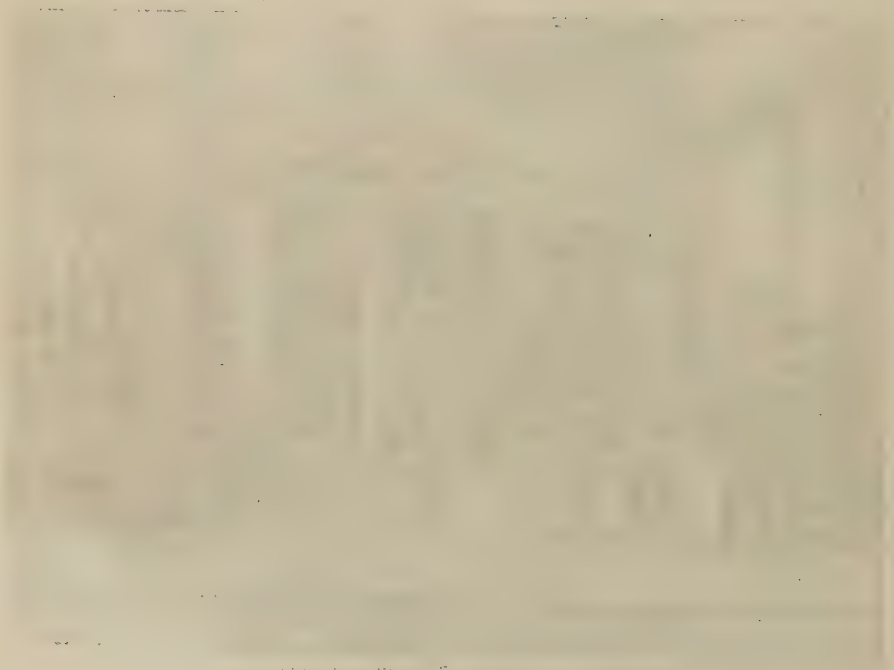

of 800 h.p., under a head of 8 ft., operating at a speed of 80 rev. per min. This plant is of unusual interest because of the low head which has been utilized. The specific-speed is 168 (748 metric). Every effort was made to keep the cost of installation to a minimum. Separate stay-vanes have been used, bolted at the top to the foundation ring. This foundation ring is built up of plates and structural shapes and is continuous with a plate-steel pit liner carrying the operating cylinders as shown in Fig. 24. Fig. 25 shows the turbine head cover. Fig. 26 shows the guide-vanes, which are built up of plate steel with cast-steel stems. Fig. 27 shows the turbine partly assembled in the shop. As in all the other units described in this paper, the draft-tubes are of the spreading type and in this installation are constructed of plate steel. In all the later installations, the draft-tubes have been of the continuous annular type with central cores continuous in contour with the runner hub.

Conclusion

It may be stated that although as a result of experience with this new form of turbine, certain minor defects have developed which have required for their correction some modifications in design, the many major difficulties which had been predicted, such as serious corrosion, vibration, instability, imperfect regulation, failure to develop the power corresponding to the head, or refusal to run under low head, have not occurred.

HIGH-SPEED SUCTION TURBINES

By Forrest Nagler,* M. Am. Soc. C. E.

Synopsis

This paper is intended to outline in a general way the experience to date with the high-speed, axial-flow type of hydraulic turbine runner for low heads. A brief comment as to the origin of this type is given, together with a statement as to the number of installations, total horse-power involved, etc. Comment is given as to the operating features that have been observed, the heads to which this type has been applied, and the present commercial range of its application.

Definition

The high-speed axial-flow type of hydraulic turbine runner, called variously in the United States the "suction runner" or "propeller runner", is generally representative of a type wherein the flow within the runner itself is in a direction mainly parallel to or "cylindrical" about the axis of rotation. (See Fig. 28.)

This is in contrast to the usual types where the flow is concentric about, but transverse to, the axis of rotation as in the Francis types (Fig. 29 left), or at right angles to the axis, but not concentric about it, as in the "tangential impulse", or "Pelton" type (Fig. 29 extreme right). The particular design for which the writer has been responsible is further characterized by a small number of blades (usually and preferably four), as contrasted with the fifteen to thirty prevalent in present conventional forms (see Fig. 29), and by the absence of a rim around the tips of the blades. In addition, there is a reduction in the width of the blade so that for the higher speed conditions there is no overlap, this being essential to highest efficiency when high characteristic speeds are reached. It is with the type thus defined, that this paper has to deal.

Historical

The place which this type of runner holds historically, particularly with reference to all other types, is shown in Fig. 31. In plotting this diagram, every obtainable performance figure has been used for the earlier forms. The writer believes this diagram to be still correct, although a paper† presented before the Society would indicate otherwise.

In that most excellent paper Messrs. Safford and Hamilton made the following statement,‡ under the heading, "The Propeller Type of Runner:"

"* * * wheels of almost exactly the same type were used many years ago, and that their high speed was appreciated. * * * Not only did Truax

appreciate what he had, but he also knew how he got it, which was unusual at this time. * * * Assuming that the measurement of the revolutions per minute and of the water was correct, and, furthermore, assuming an efficiency of 60%, which seems fair and reasonable in the light of the performance of similar wheels of the same period, a specific speed of 125 is obtained. If the efficiency has been only 40%, the specific speed would still be more than 100."

Lest this statement from so well known an authority give rise to a misapprehension as to the number of years of experience behind this type of runner, the following comments are thought to be in order. They are offered for the purpose of avoiding too rapid an application of this type to conditions for which experience has not yet proven it economical.

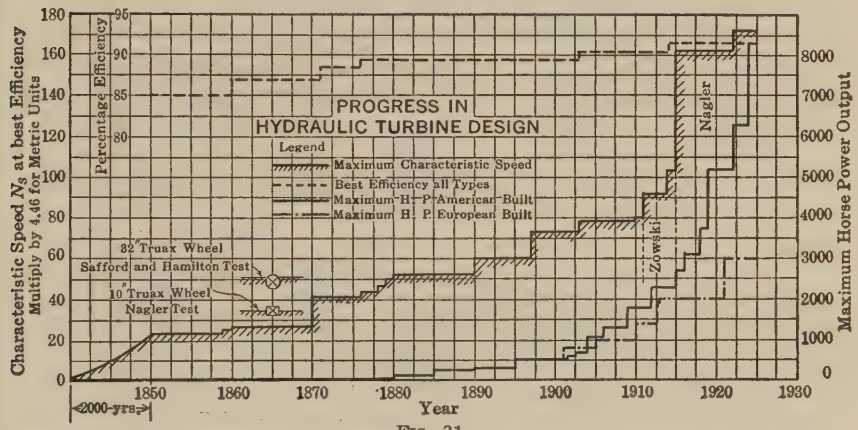

FIG. 31.

The writer possessed 10-in. wheels of the Truax and Austin (similar to the Truax) types; he made tests of these wheels and gave their results in detail in discussion* of the paper by Messrs. Safford and Hamilton. Specific speeds of 35 and 23 were obtained, using settings duplicating as nearly as possible those shown in the original Truax and Austin illustrations. Messrs. Safford and Hamilton took most vigorous exception to these tests; they secured a 32-in. Truax wheel and tested it, without finding specific speeds in excess of 60, even with a draft-tube added. The results are shown in Table 2.

* *Transactions*, Am. Soc. C. E., Vol. LXXXV (1922), p. 1310.

Replotting this comparative data on a specific speed (N_s) basis, gives the curves shown on Fig. 32(a). Another basis is given in Fig. 32(b), in which the use of unit horse-power exaggerates the comparison even as the speed basis suppresses it. The N_s basis is the fairer contrast.

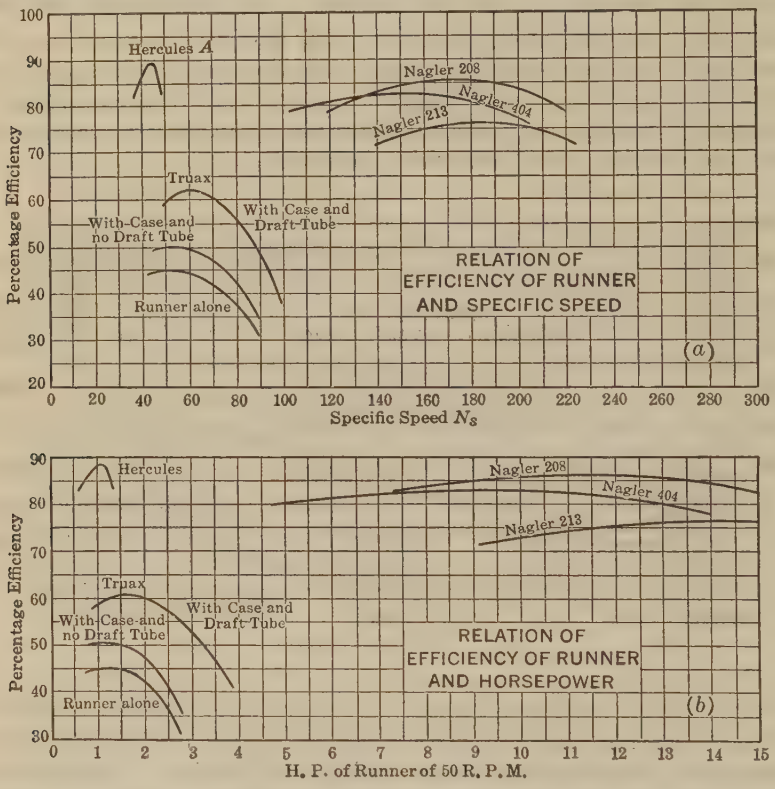

FIG. 32.

This comparison, particularly as it includes tests with additions in the form of guide-cases and draft-tubes built in the light of present knowledge, seems to the writer to show conclusively that there is some decided difference between a type of wheel which tests only to 60% efficiency and a specific speed of 61, and the modern suction type as here presented which reaches efficiencies of 90%, and specific speeds from 150 to 200, or about triple that of the earlier type.

The summary diagram, Fig. 60*, of Messrs. Safford and Hamilton, is entirely misleading. In the first place, the curve labeled "Truax" should be labeled "Truax 1876 plus Safford and Hamilton's Guide-Case and Draft-Tube, 1922". Even neglecting this point, the Truax wheel with a specific speed of 60 at the best efficiency point, represents more closely the class including the Hercules, which ranges in specific speed from 40 to 70, than it does the writer's

* *Transactions*, Am. Soc. C. E., Vol. LXXXV (1922), p. 1349.

wheel with its specific speed of 150 to 200. The Truax curve projected for over-speed extends up to a specific speed of less than 100, but it should be pointed out that the wheel which the writer contends is different, extends similarly up to 250.

Performance

The writer's experimental work on this type of runner as applied to hydraulic turbines was started in 1913. The initial plant (Fig. 28) was built in 1916, the initial Holyoke test (No. 2 521) was made in January, 1917, and the first publicity was given to this type in 1919.* At that time a total of 17 units had been built, 9 of which had been tested. To date more than 100 of these units have been built, 90 of which have a total combined capacity of 90 680 h.p. The operation of every plant has been watched most carefully and tests have been made wherever possible. The sizes have ranged from a diameter of 30 in. up to one of 156 in. The horse-power per unit has ranged from 100 up to slightly less than 5 000. The heads have varied from 22 in. up to 35 ft. and, on test plants, up to 65 ft., these high-head tests dating from 1920. The specific speeds have varied from 90 to 250, English system (400 to 1 100 metric). Holyoke tests have not been made as frequently as is customary with Francis units. The highest Holyoke efficiency reached was on a runner designed in 1920 and tested in 1923, showing a maximum efficiency of 89.2 and a specific speed at best efficiency of 175.

In general, plants have been operated with remarkably little difficulty, having an over-all continuity or reliability factor not noticeably different from that of the Francis type of unit, as far as mechanical features are concerned, and being superior to the Francis type from a standpoint of freedom from troubles due to ice, trash, and débris, either within the turbine or in the trash racks. There has been no replacement of any runner due to mechanical difficulties, nor a single instance of pitting, although practically every installation of any considerable head has been carefully watched for this trouble.

A typical performance curve is shown in Fig. 33, wherein it will be noted that a maximum hydraulic turbine efficiency of 91% is reached in the field. The runner of this particular unit is shown in Fig. 30.

Characteristics and Limitations

Practically all installations have followed the general practice conventional for the Francis type of runners, as concerns the guide-case, flume, or spiral casing. On the discharge side, practically every installation has made use of the White hydraucone regainer,† an efficient diffuser being essential by reason of the higher discharge velocity from this type of runner and the consequent necessity for as efficient a regain as possible.

One of the principal characteristics of this type of runner is its lower efficiency at partial loads, as contrasted with those of lower speed, such as the Francis type. For example, the efficiency at half load of a high-speed runner having a characteristic speed of 175 is about 66 per cent. The corre-

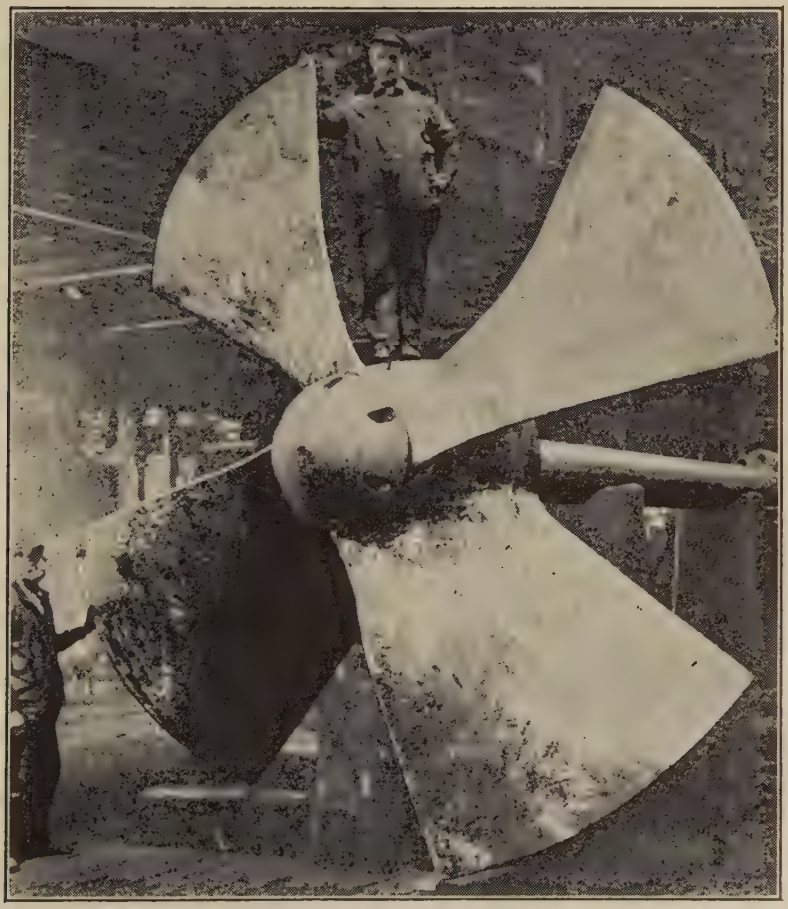

FIG. 35.—LARGEST HIGH-SPEED SUCTION RUNNER EVER INSTALLED FOR LOW HEADS.

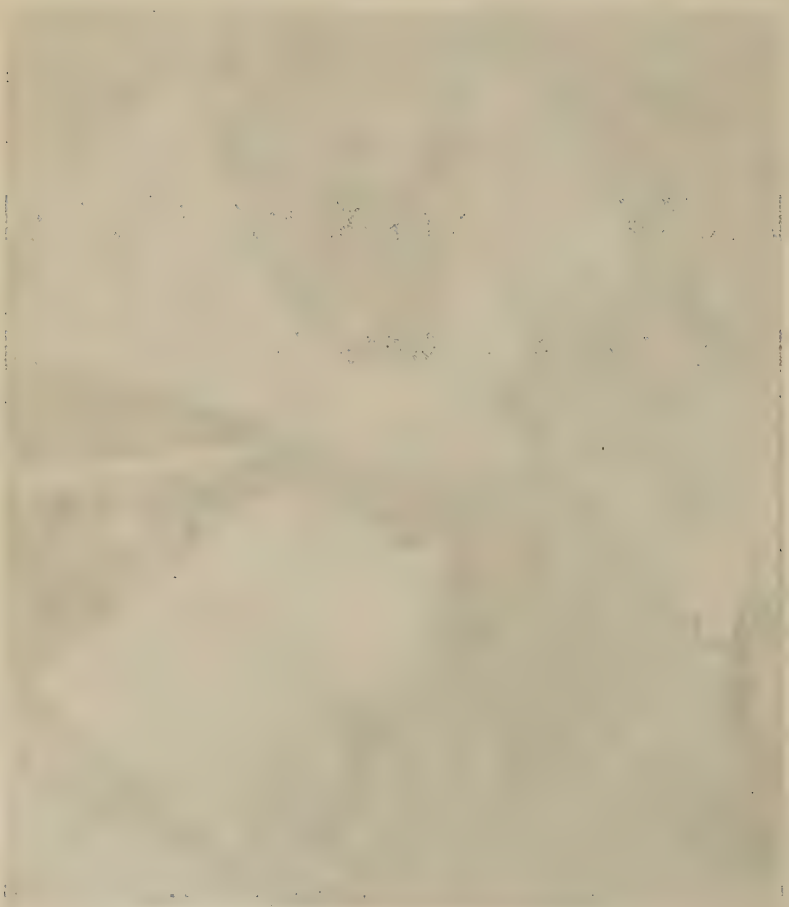

sponding efficiency at half load of a Francis runner having a specific speed of 100 is approximately 75 per cent. Francis runners of low capacity, for specific speeds of 40 or 50, have reached as high as 90% efficiency at half load, but these runners have not the characteristics that will permit of their application to low heads and, consequently, the comparison is a technical and not a practical one. In actual service, the efficiency at part gate is little or no handicap, except in plants where there may be a small number of units. It is not a considerable factor when there are more than two units in the station, because under ordinary working conditions, the operation may be maintained at or near the point of best efficiency, by intermittently shifting the load or by drawing on the pondage. This possibility combined with the fact that the over-all operating efficiency of the high-speed unit under low-head conditions (including the generator) is usually superior to that of a Francis unit, makes this type economical regardless of the saving in initial cost. Figs. 30, 34 and 35 show runners typical of both horizontal and vertical installations. The contrast in Fig. 34 between high-speed suction runners and, in the background, the Francis reaction runner which they have virtually displaced for low heads, is clear. The runner shown in Fig. 35, built for Henry Ford and Son, Incorporated, Green Island development, is 156 in. in diameter, 17 000 lb. in weight, and cast in four sections. It operates at 80 rev. per min. under a head of 13 ft.; its discharge capacity is about 85% that of the Keokuk runners, which weigh about 179 000 lb. each and measure more than 17 ft. in outside diameter.

One of the features encountered earliest in designing and experimenting with this type of runner is the possibility of varying its capacity widely without materially affecting its efficiency. It is simply a question of flattening the blade angles. European practice has apparently taken advantage of this fact and carried the application of this principle even so far as to make the blades movable under control of the governor, either simultaneously with or separately from the similar control of the guide-vane. Hydraulically, there is no question as to the results; mechanically, such a construction may come well within the standards of European practice, but the writer does not believe that it will ever become popular under American standards of simplicity, ruggedness, and high costs of labor. The need for such a construction does not enter into consideration when there are many units in the station. Governors are becoming less and less a factor, and the writer believes they will ultimately cease to enter into hydraulic turbine design to any appreciable extent, their ultimate elimination being due to the fact that hydro-electric systems will be largely interconnected with steam power where regulation is inherently less harmful to structures and to economy. It is believed, however, that this feature of variable capacity will be utilized, not so much for its advantages in increasing part-load efficiency, as for the possibilities it presents in increasing the capacity under conditions of flood or low head. This feature has been utilized in numerous installations already built, construction details being used corresponding to the adjustment of pitch on screw-pumps, which has long been the regular practice in the United States.

It has been a fairly well-defined policy of the Allis-Chalmers Manufacturing Company not to apply the suction type of runner to heads materially in

excess of 30 ft., this being an arbitrary limit, although it is supported by experimental data as well as by theoretical considerations. By departing from the pure suction type of runner with its minimum blade surface and by using blades of larger projected area, the limiting head can undoubtedly be increased, but it is the writer's belief and experience that the considerable increase of projected area, either by reason of wider blades or a larger number of blades, is accompanied by a very decided reduction of efficiency. It will undoubtedly be found that for certain installations, a definite gain in some other direction may counterbalance this particular detrimental feature and probably as experience grows, this general type will be applied to higher and higher heads and to larger and larger capacities. At present, it is not believed that it is commercially advisable or sound from an engineering standpoint to apply it to heads or capacities far outside the range of proven practice. A consistent adherence to this policy has enabled the achievement of an operating record wherein there has been no single shut-down of a unit of as much as 24-hours duration, due to conditions traceable to this type of runner.

Governor regulation has not been as perfect as that obtained with corresponding types of Francis units, but this is principally attributable to the fact that, with the higher speeds in question, the factor, $W R^2$, of the generator has been relatively lower. The regulation experienced has not differed from that obtained with Francis units by an amount unexplainable by this reduction of regulating constant.

The high-speed suction type of runner, due to its higher and sometimes critical velocities, is not conducive to as quiet a running machine as the Francis runner, perhaps in exactly the same way that the flow conditions in a Francis runner are not conducive to as smooth operation as is possible with an overshot wheel. Nothing, however, of a nature that would make it uncommercial has been experienced with this type when it is used under conditions to which it is inherently adapted, that is, relatively low head and large capacity.

HIGH SPECIFIC SPEED HYDRAULIC TURBINES IN THEIR BEARING ON THE PROPORTIONING OF THE NUMBER OF UNITS IN LOW-HEAD HYDRO-ELECTRIC PLANTS

GEORGE A. JESSOP,* ASSOC. M. AM. SOC. C. E.

The writer will indicate briefly the comparative efficiencies which can be obtained by using medium-speed wheels (of which the specific speed, N_s, is equal to about 75) and high-speed wheels (N_s equal to about 175). The efficiencies shown throughout this paper are based on model runners of the size usually tested at the Holyoke flume, that is, about 39 sec-ft. discharge at 1-ft. head. Under good conditions, it is possible to obtain better results with larger wheels in place. The data and information contained herein are obtained from tests made in the Holyoke flume and in the specially designed and constructed testing flume of the S. Morgan Smith Company.

The medium-speed runner used in these tests is of the Francis type and of normal design. The high-speed runner is a design first developed and used by The Theodore Bell Company, of Switzerland, and now being further developed and improved jointly by the Engineering Staffs of The Bell Company and the S. Morgan Smith Company. It is distinctive in that it has fewer blades than the usual high-speed wheel, and the total blade area is exceptionally large. The hub is also large, thus reducing the usual overhang of the buckets and providing a large cross-sectional area where each bucket joins the hub. An inspection of the curves will show that this wheel has its peak efficiency at a load of about 90% comparing very favorably with the slower speed runner in this respect. This is a desirable feature, because the turbine can be operated at its most economical point with a liberal allowance of power for regulating purposes, and, furthermore, this design assists in obtaining high part-load efficiency.

For very low heads (30 to 40 ft. and less), the comparison given herewith is possibly somewhat less favorable to the high-speed wheel than it should be, because usually for these heads, if a Francis runner is used, it will be of a specific speed of about 100 to 110, and will have a slightly lower peak efficiency and considerably lower efficiency at one-half to three-quarter load, than a wheel with N_s equal to about 75. Furthermore, this being a comparison of turbines only, the increased efficiency of the high-speed generator is not taken into account.

In this paper it will be impossible to present a full and complete discussion of this question, but a comparison will be given of the results that can be obtained with plants containing from two to eight units of the medium and high-speed types, together with some averages that it is hoped will be interesting and helpful.

Fig. 36 shows the comparison between medium and high-speed wheels in a 2-unit plant. Up to 50% load, of course, only one unit is in operation.

* Hydr. Engr., S. Morgan Smith Co., York, Pa.

Above 50% load, the curve is the resultant or combined efficiency of the two units. For the medium-speed wheels, when operating between 50 and 75% load, a higher efficiency can be obtained by running one wheel at maximum efficiency and supplying the remainder of the demanded power by running the second unit at the required gate-opening, than by dividing the load equally between the two units. The efficiency to be gained by the unequal distribution of load is shown by the full and dotted lines (lower left, Fig. 36). The high-speed wheels show maximum efficiency when the load is equally divided. In order to determine whether it is economical to divide the load equally or unequally between two or more units, it is necessary to calculate each plant separately, using the curves which apply. On the left of Fig. 36 curves showing the average weighted efficiency have been plotted, with the station operating from 100% load to any other load between 0 and 50%, based on the load varying at a constant rate.

The weighted efficiency for a given range of load is simply the total output in horse-power hours divided by the total input in water horse-power hours, the latter being actually computed from the discharge curves, which are not shown on the diagrams. In computing the average weighted efficiency for any given range of output, it is obviously necessary to use a definite load curve, and for purposes of comparison only a load curve has been used which varies from the minimum to the maximum output at a constant rate.

For example, if the load varies from 40 to 100%, the average weighted efficiency is about 89.5% for the 75 N_s wheel and about 84.5% for the 175 N_s wheel. If the load varies from 0 to 100%, the average weighted efficiency is about 87% for the 75 N_s wheel and about 80% for the 175 N_s wheel.

To obtain the correct efficiencies for any given station, the weighted averages must be computed according to the load curve which applies to the station. It should be noted that for most stations the comparison would be more favorable to the high-speed wheel than shown herein, because the plant would be operated for a greater length of time at high load than at low load.

The dotted curves are simply the arithmetical averages of the efficiency and are plotted to show that, at least for approximate preliminary purposes, where the load varies from about 25 to 100%, it is sufficiently accurate, perhaps, to use the more easily determined arithmetical average rather than the weighted average.

The possible exception to this statement is the high-speed turbine for the 2-unit plant, where the difference between the numerical and weighted efficiency is material. For the curves under discussion (Fig. 36), the numerical efficiency is always less than the weighted efficiency, but for the range where the curves are shown to be coincident, the differences are too small to be shown with the scale used.

Fig. 37 shows the same comparisons for a 4-unit plant, Fig. 38 for a 6-unit plant, and Fig. 39 for an 8-unit plant. It will be noted that with

FIG. 39.

a 6 or 8-unit plant, medium speed, and an output equal to 50% or more of the maximum capacity, there is very little advantage in dividing the load other than equally between the units.

Fig. 40 shows how the average efficiency increases with the number of units. The full lines are plotted using the averages for ranges of load starting with full load and decreasing at a constant rate to any percentage between 25 and 50, the efficiency being practically constant for any range between these limits. The dotted lines are plotted using the averages for a range of load from full output to zero. The average efficiency for any number of units, with the range of load varying from full load to any point between 25% and zero, can easily be approximated.

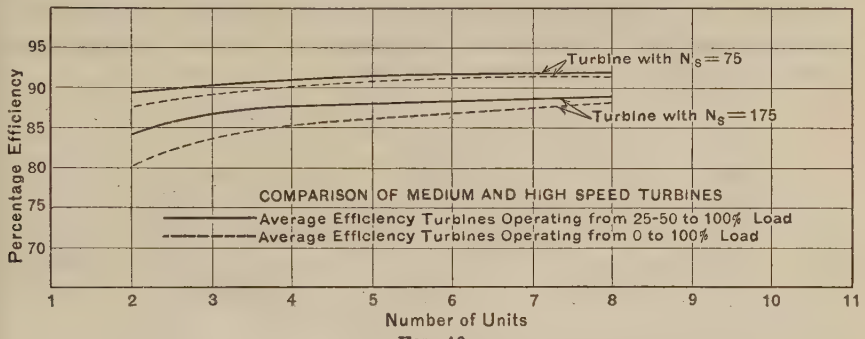

FIG. 40.

It is not intended that these curves be used to determine the average efficiency of medium or high-speed wheels; rather, the averages should be computed for each individual case. The curves simply indicate how the wheels compare in general. It must be considered that if the station is operated a greater length of time at nearly full capacity than at the low capacity, the average efficiencies will be increased over the values shown, and the averages of the high-speed wheels will increase more rapidly than those of the low-speed wheels.

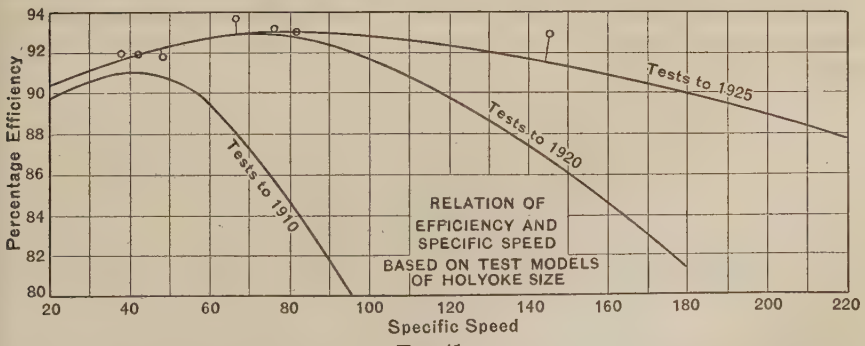

FIG. 41.

Fig. 41 shows the "efficiency-specific speed" curves for 1910, 1920, and 1925, the efficiencies being based on results which can be obtained in the Holyoke flume, on wheels of the size usually tested. Undoubtedly, it is

possible to obtain somewhat better results on large wheels, with very good settings. It is interesting to note that little improvement has been made since 1910 in low specific speed wheels, and that the improvement since 1920 is entirely in wheels with specific speeds of 80 and higher. This comparison emphasizes the reasons for present interest in wheels of high specific speed.

The comparative average efficiencies, as shown in this paper, may be considered, perhaps, somewhat unfavorable to the high-speed wheel. To bring the average efficiency of the high-speed wheel to a point more nearly equal to that of the low-speed wheel, it is necessary to increase the efficiency of the former. An inspection of Fig. 41 will show that this can be done by using high-speed wheels of a specific speed somewhat less than those selected. Not only would this give a substantial increase in the peak efficiency, but the part-load efficiencies are increased to even a greater extent.

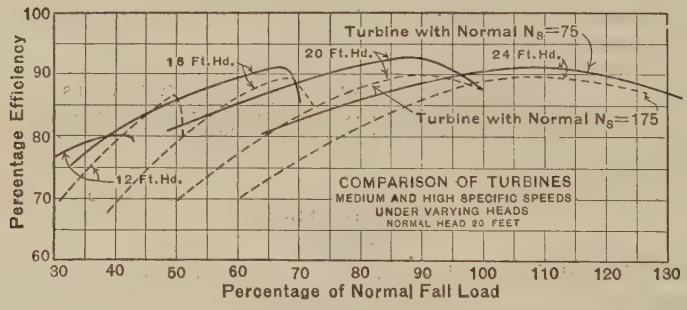

Fig. 42.

No attempt has been made to show a comparison of the average efficiencies under variable head conditions. Fig. 42 shows that the high-speed wheel has a better range at variable speed or variable head than the medium-speed turbine. The power and efficiency of the high-speed wheel hold up particularly well under low-head conditions. It follows, therefore, that where the percentage of head variation is considerable, the comparison between the two wheels will be somewhat more favorable to the high-speed wheel.

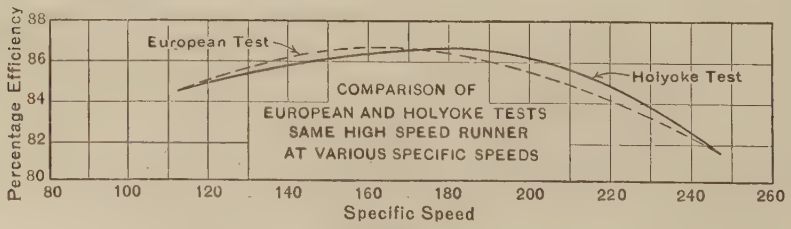

Fig. 43.

The comparison of European and Holyoke tests is a matter of general interest. Foreign engineers have always claimed that results obtained at Holyoke have been 2 or 3% higher than the correct actual. The writer has

recently had occasion to compare a Holyoke with a European test, using the same runner, draft-tube and wheel-case, and under the same head. Fig. 43 shows a comparison on the basis of the efficiency plotted against the specific speed. The difference between the tests is at no place equal to 1 per cent.

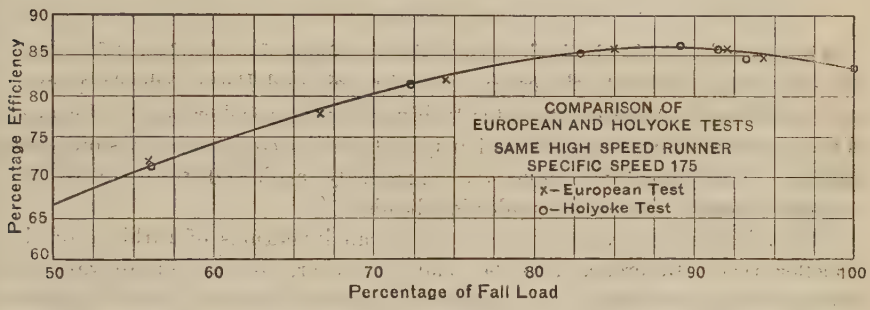

FIG. 44.

To show how the tests compare at the same speed, Fig. 44 has been plotted. The runner is about 19 in. in discharge diameter, and the efficiency differential between this size and one of normal size for the Holyoke flume is about + 3½ per cent.

SOME APPLICATIONS OF THE PROPELLER TYPE WATER TURBINE IN EUROPE

By Charles C. Egbert,* Esq.

The records of the United States Patent Office for the last fifty years will show that parallel to the cases of the Francis and Pelton wheels, pioneer work was done in America on water turbines of the propeller type. However, as the commercial demand during that period was for comparatively slow-speed machines, the propeller turbine was apparently neglected in favor of the so-called Francis type for use under low heads.

The writer has no record of early European inventions of turbines of the propeller type. Reference may be made, however, to the old Jonval type turbine which was occasionally built with rimless runners, with the blades strongly bent, or curved, to suit the slow speed for which such turbines were designed.

It was not until about 1913 that the publication of the studies and experiments of Professor Viktor Kaplan, of Brünn, drew serious attention to the possibilities of the propeller type turbine. This has resulted in its development both in Europe and America.

The commercial application of the propeller turbine in Europe was undoubtedly retarded by the World War; nevertheless, noteworthy progress has been made. This is indicated by the number of power plants in which various adaptations of wheels of the propeller type have been installed and the number of companies building that type. Furthermore, designs have been highly developed by intensive study by a number of manufacturers, coupled with much experimental work in numerous well-appointed testing flumes.

This paper makes no attempt to cover the entire subject of the application of the propeller turbine in Europe, and only gives brief descriptions of a few developments selected from data readily available.

The first to be referred to is the Lilla Edet Station (Fig. 1 and Figs. 45 to 48) built by the Swedish Government. This station contains three vertical shaft units, each of a nominal capacity of 10 000 h.p., at 62.5 rev. per min., under a normal head of 21.3 ft. (6.5 m.).

One of the turbine units is of the Kaplan type with a propeller wheel, 19 ft. (5.8 m.) in diameter, over the tips of four horizontally disposed blades (Figs. 46 and 48). It was built by the Verkstaden in Kristinehamn, Sweden. A most interesting feature of this unit is the use of movable runner blades which are pivoted in the runner hub so that the angle of the blades can be varied in accordance with the gate-opening and discharge of the turbine, thus insuring a flatter efficiency curve. The guaranteed output of this turbine under a head of 21.3 ft. (6.5 m.) is 11 200 h.p. (metric), from which a specific speed of about 144 ft-lb. units (637 metric) may be computed.

* Cons. Engr., Niagara Falls, N. Y.

The other two turbines in the Lilla Edet Station are of the Lawaczeck type (see Figs. 1 and 3), each having one runner with eight diagonally disposed blades, 19.6 ft. (6 m.) over the tips. These two units were built by the A-B Finshattan. The guaranteed output of each of the Lawaczeck turbines under a head of 21.3 ft. (6.5 m.), is 10 400 h.p. (metric), from which a specific speed of about 139 ft-lb. units (616 metric) is computed.

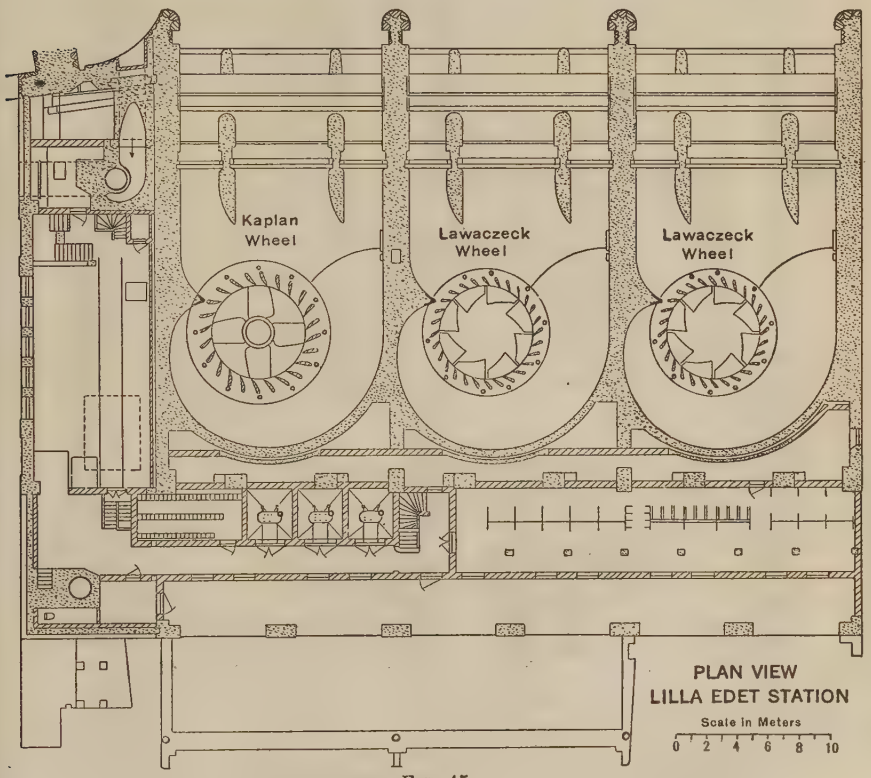

FIG. 45.

The final designs of the Lilla Edet turbines, including wheel-cases and draft-tubes, were evolved after much experimentation in testing flumes, using model runners up to 3.27 ft. (1 m.) in diameter. Various well-known forms of draft-tubes were tested before the decision to use the elbow type was reached. Fig. 4 gives the performance of the turbines at Lilla Edet.

Tables 1 and 3 show the relative capacities of some large single-runner turbines, which have been installed in different countries.

Another installation of the propeller type turbine is that in the Matte Central Station of the City of Bern, Switzerland, built by Theodore Bell and Company of Kriens, Switzerland (Fig. 56). Although this is a very small installation, the form of the runner makes it of particular interest.

the unit followed extensive experiments in the testing flume of the manufacturer.

The construction of the Matte turbine and its efficiency curve are shown by Figs. 8, 10, and 56.

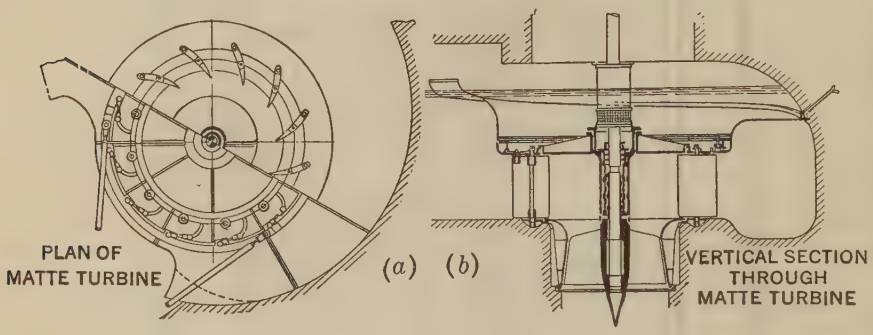

FIG. 56.

One of the latest installations is that of the Wynau Electricity Works on the Aare River, in Switzerland. This installation includes two units, each of which has a nominal capacity of 2 700 h.p. and operates at 107 rev. per min. under a variable head of 8.2 ft. (2.5 m.) to 17 ft. (5.2 m.). These units were furnished by the Ateliers de Construction Mecaniques de Vevey. Acceptance tests of these turbines indicate a maximum efficiency of 89%, with a specific speed of 165 ft-lb. units (728 metric), when operating under a head of 17 ft. (5.2 m.). Under a head of 8.2 ft. (2.5 m.), at 85% efficiency, the specific speed is given as 195 ft-lb. units (862 metric).

The design of the turbine runner was developed with the assistance of tests of models 15 in. (380 mm.) in diameter. The generator coupled to the Wynau turbine is designed for a runway speed of 2.7 times the normal speed of 107 rev. per min. In Figs. 49, 50, and 53 are shown details of the construction and performance of the Wynau turbine.

The writer particularly regrets that he is not in a position to present the developments made by Escher Wyss and Company, of Zurich, Switzerland, which have followed very remarkable results obtained in its testing flume. Fig. 7 shows one of this Company's propeller type runners having six blades.

A reluctance on the part of European turbine manufacturers and engineers to publish the results of their findings in respect to propeller type turbines, has been noted. This, perhaps, may be explained by the rapid development accomplished, leaving little opportunity to pause and review the results.

In the descriptions given, references to the testing of model runners in the development of the turbine designs have been made, which testing, it is easy to believe, is very important in respect to the propeller type runner. It appears, therefore, not without the scope of this paper to show Figs. 51, 52, 54, and 55, illustrating some of the flumes used in testing models of the turbine runners referred to by the writer.

PROPORTIONING OF UNITS IN LOW-HEAD PLANTS

By John P. Hogan,* M. Am. Soc. C. E.

In a paper delivered before the American Society of Civil Engineers on October 4, 1922,† the writer indicated certain tendencies in water power development, the more important of which were developments in storage and interconnection and a tendency toward increase in the size of units.

Increased interconnection has accomplished two important results: First, by broadening the market, it has made it possible to consider the distribution in the general market of the output of the large continuous powers of boundary streams; and, second, it has permitted the selective development for peak purposes of plants on interior streams, by removing the need for flexibility in any individual plant.

Storage on interior streams, now in process of construction or proposed, will permit not only the selective development of individual plants but will make possible the unified development of entire streams for peak power capacity.

If it is assumed that the average present installation on the interior streams is about equal to the average flow and that such a stream may be completely regulated so that the minimum flow will be brought up to the average flow, a development of this stream for 8-hour peak power will require three times the present installation. The development of regulated streams for peak power capacity requires that the time element between plants be eliminated, if possible, in order that the peak capacity in all the plants may be synchronous with the peak demand. This requires a continuous chain of plants with sufficient capacity in each pond to correct the time of travel of the water from the preceding pond. In order to make the chain continuous it is necessary on the average stream to develop relatively low-head plants which might not otherwise be economical.

In the plans for development of boundary streams a number of relatively low-head plants have been proposed. At the same time the uniformity of both the continuous and regulated flows insures the operation of larger units at full capacity and best efficiency. There is a rapidly increasing demand, therefore, for larger capacity units operating under relatively low heads.

In proportioning units for a plant, the controlling factors in determining the number of units, assuming load regulation to be provided from other sources, are: Maximum head and variation in head; character of the stream flow; speed of units; efficiency; and velocity of approach and discharge of water.

The writer does not propose to discuss in detail the variations in head and flow as they represent special problems to be considered and determined for each particular case.

For ordinary service on a fluctuating flow and varying load the Francis wheel with its relatively flat efficiency curve at varying flows is the ideal. The

* (Parsons, Klapp, Brinckerhoff & Douglas), New York, N. Y.

† "Present Tendencies of Water Power Development in New York State", *Transactions*, Am. Soc. C. E., Vol. LXXXVI (1923), p. 732.

limit of size in Francis wheels for low heads is soon reached, due to decrease of speed in proportion to the increase in size.

For a 30-ft. head the normal Francis runner operating at full efficiency should have a specific speed of about 90. For a 30-ft. head and specific speed of 90 the characteristics of normal Francis wheels of various sizes would be approximately as shown in Table 4.

TABLE 4.

Quantity of water, in cubic feet per second.	Revolutions per minute.	Electrical horse-power.
500	170	1 330
1 000	125	2 660
2 000	85	5 300
4 000	55	10 800

At the largest size shown, the size and cost of the wheel and generator become almost prohibitive. It will be readily seen therefore that speed fixes a definite limit to the economic size of Francis wheels for low-head developments. Various experiments have been made with special designs and modifications of Francis wheels to exceed the normal specific speeds, but, in the writer's opinion, they do not promise a solution of the problem.

As has been stated, designers and manufacturers, both in the United States and abroad, have put at the disposal of the constructor and operator special types of wheels to meet this situation, which heretofore have been called propeller wheels. These wheels have somewhat different designs and different spheres of usefulness, but they have the common object and result of increasing the specific speed at a slight loss in maximum efficiency.

The result is increase in speed of wheel and generator for a given quantity of water and consequent decrease in cost of wheel and generator or a decrease in the number of units, all resulting in power-house savings. A normal propeller wheel operating on a 30-ft. head will probably take 4 000 cu. ft. per sec. of water at 85 rev. per min. and therefore would be roughly equivalent to the 2 000 cu. ft. per sec. Francis wheel operating at the same speed although the propeller wheel will develop nearly twice the power.

It would appear also that the limit of size of units for low heads has been substantially doubled, if 50 rev. per min. is considered to be a reasonable minimum speed for both types. It is true that all the so-called propeller wheels, except the type with movable blades, have increasingly lower relative efficiencies at part gates than the Francis wheels. This is of no importance in continuous plants of large flow where the number of units is so great that sufficient flexibility can be obtained by combinations of units. On stream-flow plants, on the other hand, it is probable that at low flows the combinations of propeller wheels of large flow might give low efficiency and capacity at the most critical periods and that economy will dictate the use of two types of wheels of which the majority will be propellers and the minority either Francis wheels, or special wheels having characteristics similar to those of the

Kaplan wheel. This has already been done abroad for a low-head plant, as at Lilla Edet, Sweden.

In peak capacity plants it will be easier to arrive at a compromise in the number of units which at the same time will permit a large wheel and efficiency at relatively small daily flows, since it will be possible to operate for a relatively short time on a concentrated flow.

Other characteristics of the propeller type which should be considered are that they give better efficiencies at fluctuating heads and that they must be set much lower than wheels of the Francis type.

This leaves only the velocity of approach in the penstock and velocity of discharge to the tail-race to be considered. The limitations imposed by the propeller type are very similar to those of the Francis type and in low-head plants of large flow these limitations are already presenting serious problems in the design and construction of waterways.

Already, under some conditions, the provisions of adequate water passages are of more influence in limiting the size of the units than the characteristics of the wheels, and with increasing use of wheels of the propeller type in large units, the influence of these hydraulic limitations will increase. They may even be finally responsible for placing a definite limit to the increase in size of units for plants of large flow and relatively low head.

DISCUSSION

EDWARD P. HAMILTON,* ASSOC. M. AM. SOC. C. E.—The modern propeller wheel, as developed by Mr. Nagler, has many advantages over the Francis type for certain conditions. This is clearly evidenced by the large number of installations of the propeller type during the last eight years. It must be gratifying to Mr. Nagler to realize how readily what appears to be a most radical change in wheel design has come into common use.

In his paper Mr. Nagler takes exception to statement† by Arthur T. Safford, M. Am. Soc. C. E., and the speaker, that, "a wheel of the high-speed propeller type was patented and on the market fifty years ago", and that the "Green Mountain" wheel patented by Jacob Truax in July, 1860, was the forerunner of the modern propeller wheel. It was intended to show that the "Green Mountain" wheel bears much the same relation to the propeller runner designed by Mr. Nagler that the early Francis, Swain, or Hercules runners do to the modern high-speed reaction turbine, such as the Leffel "Z" model, designed by Professor Zowski.

Fig. 57 (*a*) shows the Francis runner of 1847 alongside the Zowski runner of 1913, Fig. 57(*b*), while Fig. 58(*a*) shows the Truax "Green Mountain" runner of 1860 beside the Nagler runner of 1915 Fig. 58(*b*). A glance at these photographs would seem to make it evident that the Nagler runner of 1915 would recognize the "Green Mountain" runner of 1860 as its forebear much more readily than the Zowski runner of 1913 would recognize its ancestor in the Francis runner of 1847.

The main structural difference between the Truax and the Nagler runner is the band which surrounds the former. Remove this and the wheels look very much alike. Fig. 59, taken from Emerson's "Hydraulics" published in Willimansett, Mass., in 1892, shows the Barber wheel, which was of the propeller type and had no band. Several other wheels of the Sixties and Seventies, such as the Blackstone and the Milliken, were built without bands around the runner. The Barber wheel is most interesting because, although the hub is large and the speed consequently low, the projections of its buckets and hub do not completely cover the area circumscribed by the bucket tips. In other words, the buckets fail to meet or overlap in the same way as those of a marine propeller or a Nagler runner.

Fig. 60 also taken from Emerson's "Hydraulics", shows the "Economy" wheel, made in Indianapolis, Ind. The two propeller runners have no bands. Note, also, the comparatively flat angle of the blades.

Fig. 61, taken from Bélidor's "Architecture Hydraulique", published in Paris in 1737, shows a type of wheel very common in those days in Southern France on the River Garonne and its tributaries. It was used on low falls, and was set in a masonry scroll of very much the same proportions as the wooden ones used a hundred years ago in America. Note the marked narrow-

ness of the seven blades and their failure to overlap, leaving one-quarter or more of the total runner area entirely open in an axial direction.

Fig. 62, taken from Truax's 1879 circular, shows the wheel and the form of casing that he recommended. He advised that his wheels be set in wooden rather than iron spiral casings, which, he said, cost more and were less adaptable to varying conditions.

The following extracts from Jacob Truax's "Green Mountain" circular of 1876 show a striking resemblance between the claims made for the "Green Mountain" wheel and those made for the modern propeller wheel:

"To Mill Owners.—Please do not hesitate, for I am offering you the only wheel that is adaptable for the low and common falls, and selling a wheel of the same power, using as little water, for less money than any other wheel now in use.

"I am having the most gratifying assurance from my patrons of the unequaled efficiency or superiority of this wheel over all other wheels, for common or low falls.

"This wheel has been in practical use over fifteen years, and has proved to be one of the best water wheels now in use."

"* * * the Green Mountain Water Wheel is a great money saver, for mill-owners that have low falls. One-half of the money that is laid out on a 5-ft. fall by Leffel and Risdon, or nearly all other wheel manufacturers, is saved by the use of the Green Mountain Wheel, and one-fourth on a fall of 9 to 10 ft. There is no material difference in the use of water for the same power on the same falls, but the capacity of the Green Mountain Wheel is such that much less diameter wheel is necessary to use the same cubic feet of water per minute. It being so much smaller it rotates much faster, and is impeded but little by back-water compared with other wheels. It will not wear out or break or clog with anchor ice or flood trash. Its smallness is the cause of its cheapness."

There follows a list of thirty-three installations of "Green Mountain" wheels on falls of between 4 and 10 ft., the average being 6.7 ft., after which the circular continues:

"These are a few of the low falls that my wheel is working on, and the falls are sometimes reduced one-half, sometimes two-thirds by reason of low water, or back-water caused by high water, or by being dammed up by ice below the mills, or tide-water; and fair business has been done with some of the above wheels when the fall was not more than 2 ft. They have been run when the head-water was 12 ft. above the wheel and the back-water 10 ft., leaving but 2-ft. fall, the wheel not being retarded except the loss of fall. This result is not attained by any other wheel in the world.

"It is a well established principle among scientific men that velocity doubles every four times the pressure, whether it be steam, air or water. This being a well settled fact, it will be seen, in the absence of any additional pressure, the velocity in a rotating body may be doubled by making the incline at the mean diameter four times as long as it is deep, and having thus doubled the velocity by this mechanical construction, it is plain that a water wheel of equal diameter may be made to revolve 200, 300, or 400 per minute, instead of 100 per minute, on the same fall. This is no secret, it is a plain, simple principle, and ought to be understood by every wheel builder. If the wheel builder understands this little principle or rule, he will not wonder, but say Eureka. The fact that a 4-ft. wheel may rotate 200 per minute on a fall of 6 ft. will be an easy problem to him. This principle understood, and he will not exclaim that he does not see why one wheel of the same size may run

slow and the other fast, the pressure and quantity drawn being equal. The power and high speed of the Green Mountain wheel is the application and use of this principle. It is constructed in accordance with this principle, and the use of this principle is the grand secret of the double and quadruple motion, and double and triple power, of other wheels of its size. There are none of the Green Mountain wheels that have incline planes at the mean circumference of 4 to 1, but I have used these figures to illustrate the rule, and the fact.

* * * *

"When the Green Mountain wheel was first introduced, other wheel builders in this locality treated me and my wheel with contempt, but notwithstanding this I with energy pursued my calling, put the wheel into use, kept the hammer of logic pounding, and have succeeded in driving my opponents quite out of the field. Many of them now acknowledge the usefulness and superiority of the Green Mountain Water Wheel, saying that if a man has a low fall, and fails with the Green Mountain wheel they may stop trying. For this compliment I return my sincere thanks."

The following is from an 1879 supplement to the Truax circular:

"It has double the power of the average of the other wheels of its size, and triple the motion, and free from the hindrances caused by ice and flood trash, and can, as a rule, be placed in a position ready for work for 50% of the cost of the average of other good wheels."

These statements placed alongside various extracts which might be made from the articles on Mr. Nagler's runner would show that Mr. Truax and Mr. Nagler had both worked along the same lines and had both attained a striking success in securing speeds far in excess of other contemporary types.

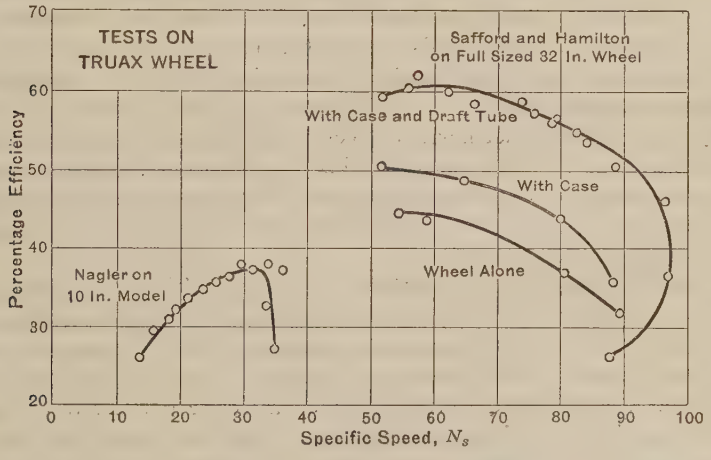

FIG. 64.

Coming now to the question brought up by Mr. Nagler as to the actual power and speed of the Truax runner, the tests made by Mr. Nagler on his 10-in. model and the results he gives in his paper are most unfair to the Green Mountain wheel. The tests made by Mr. Nagler were on a 10-in. model without any scroll-case or draft-tube and under a head of 12.90 ft. The Truax wheel tested in Lowell, Mass., was an actual 32-in. runner that had been in use

for many years in a mill in Northern New York. The results of the two tests are entirely different, as shown in Fig. 64. It is very interesting to note that the uppermost of the speaker's curves reverses and turns back toward the origin in exactly the same manner as the propeller-wheel performance curves shown by Professor Moody.

In the closing discussion* of their paper on "The American Mixed Flow Turbine" Mr. Safford and the speaker pointed out the unfairness of the Nagler tests, on account of the head used and of the omission of the casing.

Mr. Nagler feels that the use of a scroll-case and a draft-tube by Mr. Safford and the speaker made an essential addition to the Truax wheel. The Truax patent of 1860 specified both. The present casing was built to conform to the dimensions for a 32-in. wheel given in the 1876 circular from which was taken Fig. 63, showing the wheel in an iron scroll-case with a draft-tube attached. The draft-tube shown is not flaring, but to quote again from the paper† by Mr. Safford and the speaker:

"It is interesting to note that 'W. W. T.,' writing of the 'Green Mountain' propeller wheel, realized that, with a wheel of this type, a draft-tube would be of greatly increased value. He says, 'If Mr. Boyden would put his diffuser on one of these wheels, we would promise him a gain of more than 3 per cent. It would be more nearly 50.'"

The draft-tube used was far from ideal, and it actually added only about 19% to the power.

Mr. Nagler's Table 2 requires certain changes in order to be correct. He credits the Truax wheel with a maximum of 61% efficiency and 60 specific speed. It attained a maximum specific speed of 98 in the test made by the speaker and Mr. Safford. This was not reached at the point of maximum efficiency, but at a considerably lower point (37%); at a speed of 97, the efficiency was 46 per cent. It is interesting to note that while Mr. Nagler tabulates the values of efficiency and specific speed for the Truax for the same point, he uses two different points for his own wheel giving high values for both. In his original wheel he secured a specific speed of 129 at 87% efficiency, rather than the 150 of Table 2. Of course, his wheel has been greatly improved since 1915.

Fig. 65 is a copy of Mr. Nagler's Fig. 32(*a*) with a few changes and additions. The test on the 10-in. model Truax has been added, and also tests on the original Francis, the Swain, and a modern Leffel "Z" wheel as designed by Professor Zowski. All curves are for full gate. Both the Leffel and Nagler wheels show a considerably better efficiency at lower gates, but the specific speed becomes less. An inspection of these curves will show that the Leffel "Z" wheel shows a greater advance in specific speed beyond the original Francis wheel than the Nagler does beyond the Truax wheel.

It is granted that the efficiency of the Truax wheel was low. It must be remembered, however, that its efficiency compared very favorably with that of its contemporary wheels. By 1860 a great many small crude turbines were beginning to come into use, but the usual wheels in the little mills in the

* *Transactions*, Am. Soc. C. E., Vol. LXXXIV (1922), p. 1346.
† *Loc. cit.*, p. 1286.

northeastern part of the United States were the "flutter" and Rose wheels in saw-mills, and tub or scroll wheels in grist-mills and other small shops. Some undershot and overshot wheels were used, of course, but ice conditions were such as greatly to restrict their use. The "flutter" wheel probably gave an efficiency of from 15 to 25%, the Rose wheel considerably more, perhaps even as high as 60%, while the tub and scroll wheels ran from about 20 to 40 per cent. In the fall of 1923, in connection with some work at Calais, Me., the speaker ran a test on an extremely good example of tub wheel. An efficiency of 31% was obtained on the jack-shaft, equal to about 36% on the wheel-shaft.

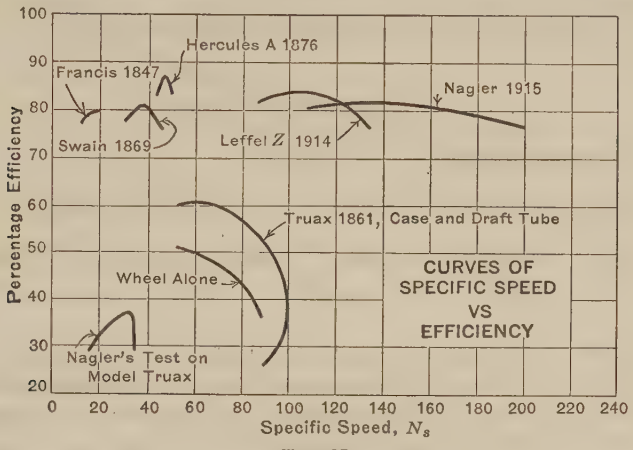

FIG. 65.

Until the latter part of the Nineteenth Century the efficiency of a water-wheel was of comparatively little importance; power was what was required. At the time the Truax wheel appeared, aside from a few tests in Philadelphia, Pa., in Lowell, and in France, the testing of water-wheels was almost unknown. It was not until about 1870 that systematic testing began.

The Truax wheel delivered the required power at a high wheel speed. Its maximum specific speed of 98 was delivered at 37% efficiency, but it gave a specific speed of 90 at somewhat more than 50% efficiency, an efficiency which exceeded that of the great majority of its contemporary wheels. Testing the wheel without the flaring draft-tube, as undoubtedly most of the Truax wheels were set, still gives a specific speed of 80 at 43% efficiency.

The water-wheels of the Sixties were not operated at their point of best efficiency. The average miller or millwright hardly would have known the meaning of the word. The wheels were operated to get the power. The maximum power shown in the test made by Mr. Safford and the speaker was developed at a specific speed of about 80 with the draft-tube and 72 without it. Unquestionably many of the wheels, particularly when under back-water conditions, were operated at still higher specific speeds.

The Truax wheel of 1861 undoubtedly had a high specific speed for its time, and this certainly was not exceeded until after 1910. The speaker feels justified in stating that a specific speed of 90 was attained, and that this speed was

attained at an efficiency which was more than ample to justify the commercial use of this wheel. Accordingly, Mr. Nagler's chart of specific speed (Fig. 32), should be modified as shown in Fig. 66.

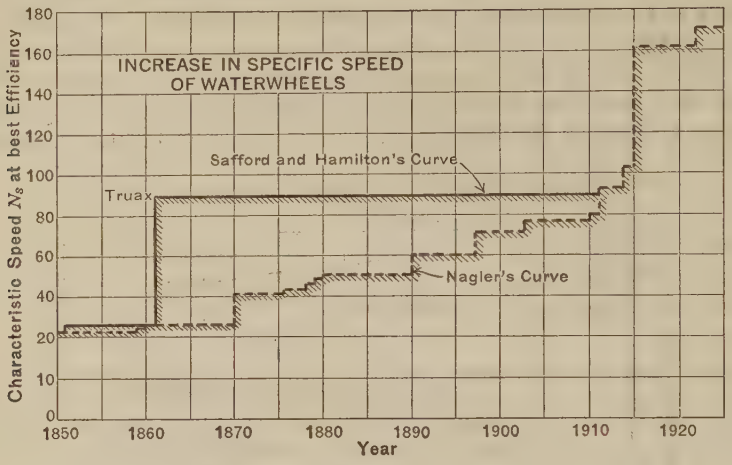

FIG. 66.

Mr. Nagler has developed a crude wheel of sixty years ago into a commercial type of wheel that satisfies present-day requirements of efficiency and mechanical construction, and great credit is due him for this. The speaker's only contention is that Mr. Nagler has not invented a new type of water-wheel, but that he has improved an existing type.

H. K. BARROWS,* M. AM. SOC. C. E.—The speaker has been much interested in the papers presented before the Power Division; the data, particularly for high-speed turbines, furnish information of value in the study of this type of wheel.

For comparison with wheels of lower specific speed the speaker has prepared Fig. 67, on which is plotted specific speed, $N_s = \frac{N\sqrt{HP}}{h^{\frac{5}{4}}}$, against the power coefficient of the wheel. The latter is P_u in the equation,

$$H\,P = P_u\,D^2\,h^{\frac{3}{2}}$$

or it is the power delivered by a 1-in. wheel under a head of 1 ft.

Curve A, Fig. 67, is plotted from data of a large number of American reaction wheels of different makes. It is an average curve, hence individual wheels will depart somewhat from it in both directions.

Curve B is an approximate curve based on the data given by Mr. Orrok in Table 1 (numbering the wheels for convenience from 1 to 8, inclusive), and by Mr. Nagler in Figs. 6 and 8 (the latter numbered 9 and 10, respectively, on Fig. 67). The point numbered 11 is for the Nagler runner at the Plainwell, Mich., plant.

* Prof. of Hydr. Eng., Mass. Inst. Tech.; Cons. Engr., Boston, Mass.

At first glance it would appear that the propeller type of wheel delivered much less power for a given diameter and head than the ordinary reaction wheel. This is due, however, largely to the different manner in which the wheel diameters are measured. With the propeller type the nominal wheel diameter is approximately equal to the outlet diameter. With the ordinary reaction wheel the nominal diameter is measured at the entrance and is considerably less in amount than the outlet diameter. If outlet diameters are used in plotting the N_s-P_u curve for reaction wheels, as shown in Curve *C*, Fig. 67, it will be seen that the two types of wheels are not greatly inconsistent in this respect. For specific speeds approximately 100 to 110, the propeller type still shows a somewhat less power coefficient than the ordinary reaction wheel.

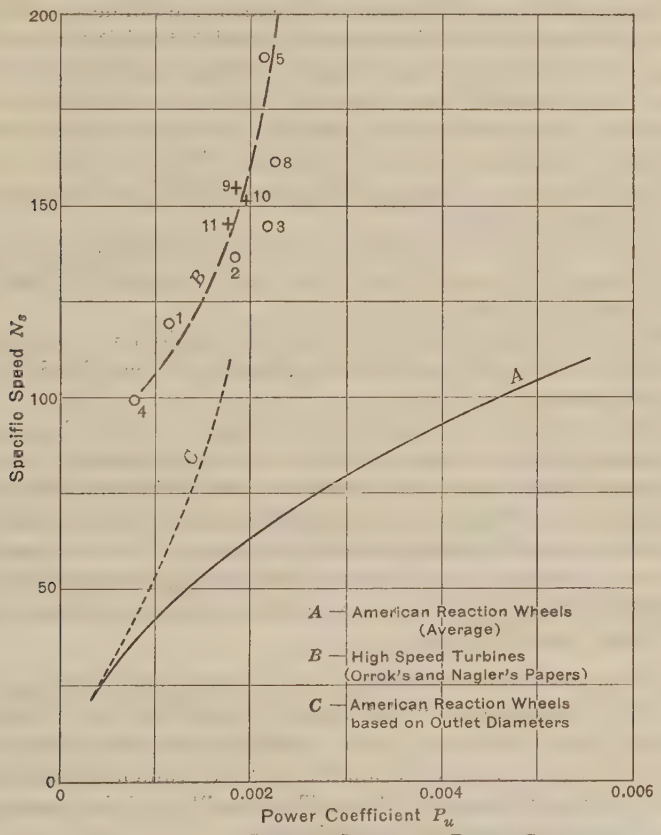

FIG. 67.—RELATION OF SPECIFIC SPEED AND POWER COEFFICIENT.

Considering the turbine as a form of orifice, it will be seen that for a given area at the outlet there should be a similar discharge and power for any given head (at, say, full gate) provided efficiencies are the same. As the propeller type is usually about 5% less in efficiency than the ordinary reaction wheel the power coefficient of the former is bound to be somewhat less.

The relatively sharp peak of the load-efficiency curve of the propeller type of wheel renders its use less advantageous where the wheel must frequently run at part load, as is usually the case. Although under some circumstances it may be practicable to run a propeller type of wheel fairly steadily at best gate, the speaker agrees that this is likely to be difficult of attainment with the ordinary hydro-electric plant.

W. M. White,* M. Am. Soc. C. E.—The papers contained in this Symposium on the important subject of high specific speed hydraulic turbines, have been very comprehensive. The speaker had the pleasure of visiting the Lilla-Edet plant to which reference has been made and was greatly impressed with the tremendous size of the conduits leading the water to and from the wheels. The construction has been considerably delayed due to labor troubles. The Verkstaden Works in Kristinehamn, Sweden, the builders of the turbines for this plant, extended an invitation to the speaker to visit the works and he had an opportunity of seeing the turbines in course of construction. There is more need for the movable vane runner in Europe than in America, because in this country such a network of power lines exists that nearly every plant constructed can be operated to its full capacity as long as water is available.

Mr. Moody has given a formula which throws additional light on an interesting and important subject.

Mr. Jessop's paper has conformed more exactly to Mr. Orrok's suggestions as to scope than any of the others and the speaker is sure that his presentation will be of value.

Mr. Nagler has done valuable work and has made a real contribution to the art. His type of runner enables the development of lower heads than would otherwise be possible.

The high-speed runner, as designed by Mr. Moody, seems to be a type which lies in the intermediate zone between the "Z"-type of Leffel wheel and the four-bladed "Nagler" wheel. It is to be hoped that the Engineering Profession will encourage further development along these lines by giving protection to those making inventions and pursuing development work. The only way a manufacturer has of recovering expenditures made for developments such as have been discussed in these papers is by having the exclusive use of the devices thus developed for a reasonable time.

Lewis F. Moody,† Esq. (by letter).—As a supplement to the material contained in the Symposium, on "High Specific Speed Hydraulic Turbines," the writer would call attention to a paper, which appeared shortly after the presentation of the Symposium, by Franz Staufer, of Munich, Germany, entitled "Influences on the Efficiency of Water Turbines."‡ A brief abstract of this paper by C. Reindl has also been published.§

Referring to the writer's discussion of the variation of efficiency with size of turbine, it is interesting to note that Mr. Staufer has taken up this

* Mgr. and Chf. Engr., Allis-Chalmers Mfg. Co., Milwaukee, Wis.

† Cons. Engr., I. P. Morris Dept., The William Cramp & Sons Ship & Engine Bldg. Co., Philadelphia Pa.

‡ *Zeitschrift des Vereines deutscher Ingenieure*, March 28, 1925.

§ *Die Wasserkraft*, May 1, 1925.

same subject along similar lines, has developed a formula of the same form, and has arrived at the same numerical value of the exponent of the ratio of diameters appearing in the formula.

Mr. Staufer mentions the point noted by the writer that the change in efficiency of water turbines as affected by diameter and head, as first formulated by Camerer, was based on the formula of Biel. Instead of using the Biel formula, Mr. Staufer, proceeding along the same lines as the writer, has based his work upon the exponential expressions for the loss of head in fluid flow and using numerical values taken from the work of Reynolds, Schiller, Jakob, and Erk, has derived the formula:

$$e' = \left[1 - \left(1 - \frac{e}{e_m}\right)\left(\frac{D}{D'}\right)^{c_2}\left(\frac{H}{H'}\right)^{c_2^2}\right] e_m'$$

Staufer's notation being here modified to correspond to that used by the writer. Adopting a value of $\frac{1}{4}$ for the exponent, c_2, this formula then becomes:

$$e' = \left[1 - \left(1 - \frac{e}{e_m}\right)\left(\frac{D}{D'}\right)^{1/4}\left(\frac{H}{H'}\right)^{1/16}\right] e_m'$$

In this formula, e_m denotes the mechanical efficiency of the turbine, that is (expressed in percentage), 100 minus the percentage of loss in mechanical friction in bearings, etc.

It will be noted that the effect of change in diameter as derived by Mr. Staufer is the same as that proposed by the writer. A considerable number of comparative tests investigated by the writer indicate that the exponent of the ratio of heads should be even smaller than the figure of $\frac{1}{16}$ derived by Mr. Staufer. Unless the ratio of heads is very great the change in head is of only minor effect. Since the mechanical losses in most turbines of ordinary sizes are very small, it is believed that these losses need not be separated from the total loss, and it has been found that the simpler form of expression proposed on page 628 of the writer's paper can be applied satisfactorily to the total efficiency of the turbine with the value of the exponent as there stated, namely, $\frac{1}{4}$.

Mr. Staufer's paper also includes some interesting results of recent tests on a high-speed propeller type turbine.

Forrest Nagler,* M. Am. Soc. C. E. (by letter).—In reviewing the papers and discussions, more or less confusion in the understanding of the subject of high-speed runners seems to be attributable to an assumption that the various names applied to this type are synonymous. The term "high-speed turbines" or "high specific speed turbines" is not definitely descriptive, nor does the term "propeller type", "axial flow type", "suction type", or any of the individual names attached to the type definitely fix a place in the specific speed scale. For example, high specific speed turbines may have a specific speed of 10 for impulse

* Hydr. Engr., Allis-Chalmers Mfg. Co., Milwaukee, Wis.

turbines, 100 for Francis turbines, or 200 for suction turbines. Similarly, a Moody runner may aparently have a specific speed of 90 or 190. A propeller type turbine or an axial flow turbine may apparently have a similar range of specific speed. The suction type turbine is likewise open to criticism, but it is the most definite term, because it describes a certain characteristic which enters not at all, or to a negligible extent, in conventional forms of turbines; and, furthermore, the name signifies a characteristic which gives an indication of its specific speed and design limits, the latter being based on barometric limits.

The writer has no solution to offer for the confusion arising from the broadness of the terms used to identify the various runners. It is desired, however, to point out that a propeller turbine does not necessarily indicate a high specific speed turbine, nor does a suction turbine necessarily cover a type having a specific speed of less than about 140. Naturally, the design features of any one of these types merge gradually into those of another type, without a definite line of demarcation. The foregoing discussion is offered because of the very great need of definitions to permit avoidance of generalizations that are technically incorrect.

The various papers, particularly those by Messrs. Orrok, Moody, Egbert, and Jessop, should go far toward improving the understanding of American engineers as to the new runner types, their range of characteristics, and their limits of application. Mr. Moody's paper contributes one valuable tool much needed by all those concerned with the construction or operation of water power plants, namely, his simplification of formulas for the variation of turbine efficiency with the variation of size. Previous comparisons, if at all practical, have been largely empirical and the need of a simplification of the intricate and clumsy algebraic expression of the laws has been very great. It would be well if Mr. Moody's expression for the variation of efficiency with the size of units could be embodied in present test codes, not so much by reason of its peculiar application to test code uses, but because that is probably the most practical place for its inclusion as a reference of interest. It has a certain utility in testing, on account of the growing tendency toward careful comparison between model tests and power plant tests.

The runners which Mr. Moody shows are very interesting. The newness of the art of building this type of wheel is indicated by the fact that Mr. Moody's experience is apparently not in accord with that of the writer, who, for example, has not been able to secure as high an efficiency at the higher specific speeds, that is, of more than 150, with the large projected blade area shown in Mr. Moody's design. Conversely, all the large projected-area runners have been very definitely improved in efficiency as their areas were reduced. Not only is this tendency logical, from considerations of wetted surface, the reduction of which has been largely responsible for the development of specific speeds in excess of 125, but the fact is checked absolutely by experience with marine propellers, where the initial perfection of steamship drive resulted from reduction of the blade area. Similar tendencies are found in the development of windmills, sails, electric fans, and blowers. Its parallel is lacking in the case of the steam turbine only, because the primary consideration of steam

turbine design is that of keeping the speed low, rather than high, and because friction loss is to a greater or less extent regained thermally.

Mr. Hamilton is agreeably persistent, but the main basis of difference in opinion is found in the writer's previous comments as to definitions of types. Had there been any positive knowledge of how to secure high specific speed or had specific speeds even remotely approaching 100 ever actually been obtained, there seems to be hardly a reasonable doubt but that the principles involved would have entered into commercial practice, at least to some extent, without waiting 40 or 50 years. Mr. Hamilton's revision of the specific speed curve after 1861, as given in Fig. 66, is not in accordance with established practice and even the inclusion of a single point approaching a specific speed of 100 between 1860 and 1870 would still effect the curve but slightly, because that point did not enter into subsequent practice.

The writer does not take exception to Mr. Hamilton's statement that Mr. Truax knew what he had and knew how he got it. Exception is taken only to the assumption that he had any particularly high specific speed. The original statement by Messrs. Hamilton and Safford in their paper on "The American Mixed-Flow Turbine and Its Setting",* credited Truax with a specific speed of 125. The writer's tests showed less than 50 and Mr. Hamilton's tests only 50 or 60 at the point of best efficiency, with this point so low as to result almost inevitably in the wheel being discarded. The Barber wheel could be set so that, with the proper draft-tube, it might show specific speeds of more than 100. It is doubtful whether either the Truax or Austin could ever do so. Their principal lack is in their adherence to the helical blade form as contrasted to the curved form that is so essential to producing the suction principle on which high specific speed depends. This deficiency is exactly comparable in an aeroplane to the sacrifice of, roughly, one-half its lifting power which would result from using a flat wing in place of a curved or ærofoil section. The quoted statement of aviation engineers to the effect that, with sufficient power, one could fly a plank, has no particular counterpart in runner design, however, and nothing that can be applied to the Truax runner as built can bring it into the class which Mr. Hamilton wishes to place it.

The writer is rather surprised at Mr. Hamilton's statement that "until the latter part of the Nineteenth Century the efficiency of a water wheel was of comparatively little importance". Francis' efficiency of 80% in 1847, and Swain's, of 80% in 1869, according to Mr. Hamilton's diagram, Fig. 65, as well as Risdon's, who certainly was not asleep prior to 1873, offer interesting comments on this point.

Mr. Hamilton criticizes the writer for using a specific speed of 150 for his original high-speed runner, stating that it should be 129, rather than 150. Referring to the original paper entitled "A New Type of Hydraulic-Turbine Runner,"† it will be found that two runners are given, one of which had a specific speed of 154 and the other of 125, as tested at Holyoke several years previously. The writer has never used anything but the point of best effi-

* *Transactions*, Am. Soc. C. E., Vol. LXXXV (1922), p. 1237.

† *Transactions*, Am. Soc. C. Mech. Engrs., Vol. 41 (1919), p. 829.

ciency in comparing runners. If Mr. Hamilton wishes to make tests on the writer's high-speed runner as he has done on the Truax, it is a question of comparing a speed in excess of 200 with one below 100, these being the relative maximum points obtainable. The fact of "W. W. T.", according to Mr. Hamilton, stating that if a diffusing draft-tube should be added with the Truax wheels there would be a gain, does not justify Mr. Hamilton in so adding a draft-tube and crediting it back to Truax as of 1861. The writer has found no instance of any specific speed ever having been obtained in excess of 60 at the point of best efficiency, or 90 at the maximum possible obtainable point, as far back as Mr. Hamilton outlines. If he wishes to include a point as high as 90, as shown in Fig. 66, the basic curve should likewise be raised to cover the maximum obtainable specific speed, disregarding efficiency entirely for the various runners which made up the basic curve.

In Fig. 67, Mr. Barrows contributes a very interesting comparison of wheels. He correctly analyzes Curve *A*, in that it is based on an uncomparable method of measurement. As a matter of fact Curve *A* could be readily moved 30 or 40% to the right, simply by taking the runners on which it was based and cutting back their inlet. Similarly, the high-speed runner curve could be moved 100% to the right by taking a mean radius in place of the outside diameter. As a matter of fact Curves *C* and *B* are truly comparative. The writer does not quite agree with Mr. Barrows that the difference in the position of the curves, which means difference in power coefficient, is attributable to a difference in efficiency. The two turbines may be forms of orifices, but they may differ widely in their coefficients. Centrifugal force opposes the flow in the one and does not oppose it in the other. This gives one of the most positive and inherent obstacles to obtaining a large power coefficient with a Francis type with its more or less radial inflow.

This consideration of power coefficient brings up a very interesting problem —one which the writer has frequently presented to students on this subject. In its simplest elements it may be stated thus: What is the maximum theoretical power that can be developed from an orifice 1 in. in diameter under 1-ft. head?

Mr. Jessop's paper should serve to owners of power plants as an excellent example of what can be accomplished by proper operation. Probably one of the greatest wastes to-day is due to a lack of appreciation as to what it means to regulate units over a wide range of gate-opening. The curves shown, particularly those of Figs. 36 to 41, illustrate this operating feature splendidly, although the writer would point out that it is not fair to compare a Francis turbine of 75 specific speed with a high-speed turbine of 175 specific speed, as they would not be used for the same plant. The former is adapted to heads above 50 ft. and the latter to heads below 20 ft. If a Francis runner of 110 specific speed is compared with a high-speed runner of 150 specific speed, the contrast would be more appropriate and the difference less exaggerated.

The writer is rather surprised at Mr. Jessop's conclusion that identical units should be operated at varying loads for best total economy. Most cer-

tainly this is not the case except when the load is such that the gates of one of them may be closed entirely. The general law seems to be that with any type of identical units having efficiency curves that are convex upward, all units carrying load should be operated at the same load. Unfortunately, Mr. Jessop's system of operation is only too frequently encountered in practice, due to the fact that it is not particularly easy to measure the relatively small gain for moderate shifting of load with the usual type of board instruments.

Mr. Jessop's comparison of European and Holyoke tests is excellent and has long been needed, not so much for the information of American engineers as for answering a more or less prevalent belief among European engineers to the effect that American test methods are not correct. The greatest progress can be obtained only by co-operation and anything that will make for mutual confidence between the two groups of engineers cannot help but be advantageous. Hence, the value of Mr. Jessop's Fig. 44.

Paper No. 1583

THE ENGINEER AS A RAILROAD EXECUTIVE*

By Julius Kruttschnitt,† Esq.

To judge correctly of the qualifications of a man for the position of "Railroad Executive", a comprehensive survey of the duties devolving on the chief executive officer of a railroad under present-day conditions and of the difficulties which he has to overcome, must be made. Not only must the problems that require solution be considered but the limitations imposed by law on the revenues of railroads and the extent of control of their expenses that the executive is permitted to exercise. It seems appropriate, therefore, to introduce a quite full outline of the problems that confront the responsible managing officer, to show the extent to which so far he has solved them, and to what extent they remain unsolved, and then to show how the engineer has risen to new responsibilities, and what recognition stockholders and directors of railroads have accorded to his fitness to administer their properties.

Fundamentally, a railroad is a huge manufacturing plant designed to convert the energy locked up in fuel into work for transporting persons and property on specially designed roadways. The energy conversion is by means of individually operated locomotive units, and the success of the entire plant, measured by the spread between production costs of output, measured in passenger-miles and ton-miles, and in selling prices, depends on the efficient working of each individual unit.

To attain the maximum or even moderate success in creating a margin between the cost and sales prices of output, the necessary executive and administrative work can best be done by men specially trained in those branches of knowledge that contribute most to the efficient operation of railroads, on the degree of which depends success or failure; and the most important duty of the chief executive is to select his official staff so as to attain the best results.

* Address before the New York Section of the American Society of Civil Engineers, in Joint Meeting with the New York Sections of the American Institute of Electrical Engineers, the American Society of Mechanical Engineers, the American Institute of Mining and Metallurgical Engineers, and the New York Electrical Society, March 18, 1925.

† Chairman, Executive Committee, Southern Pacific Co., New York, N. Y. Mr. Kruttschnitt died on June 15, 1925.

To pass intelligently on the qualifications of his staff and their recommendations that may reach him—in other words, to avoid being a mere "rubber stamp" to approve whatever is laid before him—requires a fair knowledge of the functions of each department head by the chief executive.

At the outset, the speaker will explain the causes that have brought about the epochal changes in the conditions of the railroads in the first quarter of the Twentieth Century, conditions that have obstructed successful operation to an extent never theretofore encountered, and then show how American talent has adapted the railroads to these new conditions and thus far has averted bankruptcy and ruin.

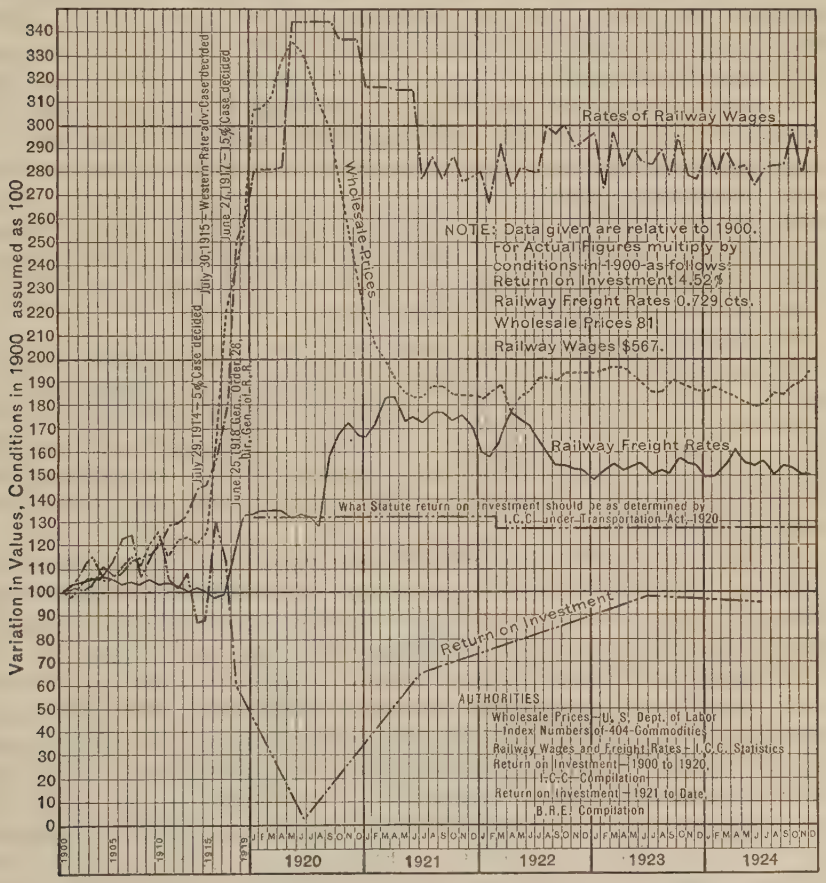

FIG. 1.—RELATION OF PRICES, RAILWAY WAGES, FREIGHT RATES, AND RETURNS ON INVESTMENT FOR TWENTY-FIVE YEARS COMPARED WITH DATA FOR 1900.

From Fig. 1 it will be observed that the rise of prices of all commodities throughout the country, started by the outbreak of the World War in the summer of 1914, culminated in the United States in May, 1920, when the index number of wholesale prices showed an increase of 236% above the

corresponding number in 1900. Starting from the base index number—taken as 100 in 1900—there was a slight fall in 1901, but in 1902 prices were 4% above those of 1900 and, with some reversals, the rise was continuous to the outbreak of the World War, when they were 20% higher than in 1900. At the date of America's entry into the war, the index number of wholesale prices was 120% above that of 1900. The fall from the peak of 236% over 1900 in 1920 was rapid to 83% above 1900 in the middle of 1921, since which time there have been fluctuations leading to the figure of 94% above 1900 in December, 1924.

During the 17 years from 1900 to 1917, the average railway freight rate in the United States remained nearly stationary. True, there were fluctuations that affected the average but never sufficiently to raise it over 5 to 7% above 1900, so that when the United States entered the World War the average freight rate was almost exactly the same as it was 17 years theretofore, but in 17 years average prices had risen 120% and wages of railway employees had risen 77 per cent. At the beginning of the century, 25 years ago, the average operating ratio for all the roads of the United States was 65 per cent. Under Government operation it rose in 1920 to 94.3% and for the twelve months of 1924, after four years of private operation, it fell to 76.14 per cent. These data are quoted to show how the spread between revenues and expenses has shrunk, and how narrow a margin exists at the present time out of which to pay interest on obligations and dividends on stocks.

It will be observed that the percentage return on investment that was 4.52 in 1900 substantially vanished in 1920 on the return of the railroads to their owners by the Government, and never since that time has equalled the 1900 return. For 1924 it was only 96% thereof, or 4.35%; since then it has fallen still farther below the statutory return prescribed by Congress as reasonable and allowable, 6% from March, 1920, to March, 1922, and 5.75% from March, 1922, to date.

The figures quoted show the wide difference in the kind of managing talent required on railroads now and 25 years ago. At the end of the Nineteenth Century, 35 cents net out of every dollar could be turned into the Treasury, while at the present time only 24 cents, or 32% less, can be turned in. It requires the closest kind of management and the services of very much more highly trained executives to meet all money requirements other than mere operating expenses with only 24 cents out of every dollar. To obtain the most work out of fuel, the largest material item of operating expenses, taxes the efforts of substantially every department on a railroad, and to obtain the best results requires the highest talent in a great many different branches of engineering. The course of Civil Engineering in leading universities embraces courses in the allied sciences of Mechanical and Electrical Engineering, and the important principles of physics, chemistry, geology, and economics, so that the executive who has enjoyed the training afforded in a civil engineering course is peculiarly well fitted for co-ordinating and guiding the numerous operating activities on railroads and for securing the maximum output of salable products at minimum costs. An analysis of operations that produce transportation units will show that the engineer who has been trained

to secure desired ends in the most practical, efficient, and least expensive way can best contribute to the success of a railroad enterprise, and will indicate the directions in which he should prepare himself in college for executive duties, and will correspondingly indicate to the owners of railroads, other things being equal, the qualifications to seek in managers.

To repeat—viewing the railroad as a manufacturing plant designed for the sole purpose of creating the maximum of transportation units out of the minimum of fuel units, the greatest efficiency will be attained by that railroad the executives of which co-ordinate best all departments and concentrate their activities on increasing output, from the sale of which the railroad must secure its revenues.

Enumerating some of the activities of a railroad will show how numerous are the demands made on a chief executive, and at the same time will indicate to a certain extent how the problems that confront him have been partly solved or are still demanding study for their solution.

I.—Executive Department

The wise executive will spare no expense in establishing an Accounting Department to keep track of earnings and expenses; to record the history of operations; to act as general inspectors; to expose poor results as prerequisites to their correction; to work up promptly cost data of every important item of operating expense and as promptly to put them in the hands of all concerned. While the experience of the men who make the decisions will usually keep them from going far wrong, yet in matters involving millions of dollars in both capital and operating expenses, a railroad officer should not be satisfied unless he has definite figures on which to base decisions. The record traffic handled with record efficiency in 1917 was the response of the railroads to the monthly data sheets first issued by the Railroads' War Board; these are now issued in even more detail by the Interstate Commerce Commission and the Bureau of Railway Economics. Fuel accounts kept with individual engineers and firemen and locomotives furnish railroads with data from which to decide definitely what type of locomotive is the most economical for their use, and whether the expense of applying and maintaining some of the many fuel-saving devices is warranted.

"The location of a railroad is giving it its Constitution. It may be sick almost unto death with accidents of construction and management, but with a good Constitution it will ultimately recover." The board of directors, advised by the chief executive, must pronounce on the location of the railroad between its termini; it allots the amount of money to be spent on construction; fixes the grade and curve systems, because the ideally perfect railroad, between given points, should be absolutely straight and of uniform grade, that is, devoid of undulations in alignment or profile. The expense of operation will increase in proportion to the grade and curve resistance involved in departures from the ideal line, and the extent of departure must be authorized by the board, on which devolves the duty of providing the money for construction. Whenever a ton weight is lifted 1 ft., an amount of work equivalent to moving it 333 ft. over a straight, level track is spent; and every time a ton weight of

train is forced through 100 ft. of 1° curve, the work done in deflecting it from a straight to a curved path is equivalent to moving the same ton over 16⅔ ft. of straight, level track. The equated length of the old line of the Central Pacific between Ogden and Lucin, Utah, compared with the new Lucin Cut-Off line is as 280 to 129 miles; 1 lb. of fuel on the new line moves as much tonnage as 2.2 lb. on the old one.

The Executive Department must determine the justifiable outlay to reduce grades and curvatures on existing lines, as obviously the expenditure necessary to obtain a straight line between two points without any undulations in grade might be commercially prohibitive. It is, therefore, of the greatest importance for the commercial success of a railroad to balance the money cost of approaching as nearly as possible ideal conditions with the expected benefits.

Motive power can often be economized by expensive physical improvements, such as installing automatic block signals, re-designing terminals, modernizing roundhouses so as to utilize the residual heat from incoming locomotives to raise steam on outgoing ones, and increasing the number and lengths of sidings to save delays on the line. On the chief executive rests the responsibility of balancing the interest, maintenance, and depreciation costs on large capital expenditures against possible savings, and of providing the necessary capital if the investment is justified.

II.—Traffic Department

The Traffic Department is the sales department of the railroad, and its contract specifications as to loads in cars and character of service exert a profound influence on net earnings. It requires 41% less power to haul 50 tons of lading in one car than in two cars of the same class and weight, and 53% more power to haul a given load at 40 than at 20 miles per hour.

III.—Maintenance of Way Department

The resistance to traction of locomotives and cars varies between wide limits with the condition of the track. The train resistance figure commonly used of 6 lb. per ton (2 000 lb.) at low speed assumes track in good condition. It may very easily be two or three times that amount on track laid with light rail, poorly maintained, in bad surface, and with low joints, etc. The heavier the rail and the better the ballast, the easier it is to maintain good alignment and surface, the less will be the deflection under loads, and the less will be the work required to force the wheels out of the depression caused by weak and yielding joints.

IV.—Maintenance of Equipment Department

About one-fifth of all locomotive coal (in 1921 this amounted to 25 000 000 tons) was consumed when the locomotive was not doing useful work: in firing up, in waiting for trains, in standing on sidings and passing tracks, in delays at terminals, drawing fire, and waiting at ash-pits. This consumption is not productive, nor is it all waste. By re-designing terminals and increasing the lengths and numbers of sidings the waste can be minimized. Ingenious graphs on which obstructions to traffic are likened to obstructions to the flow of water

in incrusted pipes have proved of great assistance to indicate how to increase the capacity of the line and defer double-tracking.

In designing locomotives, the features exercising the greatest influence on fuel efficiency are: Careful and expert proportioning of engines, boilers, fireboxes, grates, flues, draft appliances, so as to produce by their combination the most perfect device to extract from fuels their full heat contents. Barely 8% of the energy in fuels is now extracted and converted into work.

Although it is customary to speak of the waste of fuel in the average locomotive, the extremely unfavorable conditions under which it is required to work must not be forgotten. Space limitations have thus far prevented the successful use of condensing engines, and this has deprived the locomotive of the advantage of 12 to 13 lb. additional effective cylinder pressure. It is driven through all kinds of weather at high speed, so that radiation losses are excessive. To meet the demands made on its boiler for steam, explosive draft must be used, which expels much unburned fuel from the firebox; the resultant effect of all this is evidenced in low thermal efficiency.

With the increase in the power of locomotives and the use of higher steam pressures, mathematical talent instead of "rule of thumb" has been called on to compute stresses and to proportion parts. Questions as to the adoption of alleged improvements are difficult to decide, as they involve first cost, interest, maintenance and depreciation, their possible effect on engine failures, and the idle time of locomotives while undergoing repairs. Sometimes economy of operation is sacrificed to facilitate adjustment and repairs, as when outside valve gears replaced the original Stephenson link motion.

The practice of buying locomotives regardless of their adaptability to special service, as was done during Federal control, simply because they could be built in quantity at some reduction in cost, is recognized by competent judges as the poorest kind of economy.

The brake thermal efficiency—or the percentage of energy in the fuel transformed into work—for various engines is as follows:

Reciprocating, condensing, stationary steam engines (boilers excluded)	19.0%
Steam turbines	19.2%
Average of eight large power plants (boilers included)	13.3%
Non-condensing steam locomotives at maximum capacity, equipped with proven fuel-economizing devices	7.3 to 8.1%

Some of the problems that have been closely studied and have been solved to a greater or less extent are:

Brick Arches.—Brick arches built into the firebox mix the entering air thoroughly with the combustible gases rising from the fire and save on some types of locomotives about 12 per cent.

Superheating.—The advantages resulting from the use of superheated steam are due mainly to (*a*) prevention of cylinder condensation; and (*b*) larger volume of steam per pound.

Since the cylinder takes the same volume of steam per stroke for the same cut-off, it is obvious that substantially less pounds of steam will be used for the same work done. Superheating may save 20% of the fuel.

Feed-Water Heaters.—Feed-water heaters utilize waste heat to raise the temperature of the feed water, thereby relieving the fuel in the firebox from heating the cold feed water from an average of 60° Fahr. up to 220° Fahr. and saving about 10 to 14% of the fuel.

The combined average effect of these three devices in saving fuel on passenger and freight locomotives of various types and speeds in actual service is:

Arch	9 %
Superheater	20 %
Feed-water heater	10 %
Combined	34.5%

These figures vary widely for different locomotives, speeds, and classes of service.

The savings claimed for the various fuel-saving devices are gross figures. The cost of application is quite large, and in some cases not justified by the age or obsolescence of the locomotive; in others, it is beyond the financial ability of railroads to apply them; hence care must be taken to balance the cost of interest, maintenance, and depreciation against the value of the fuel saved. The net saving so determined—not the gross—will show whether or not the money to provide the appliances can be providently expended. Experience shows that thus tested the gross saving of superheaters is reduced from 20 to about 17.4%; of feed-water heaters from 10 to about 6 per cent.

Boosters.—Under normal conditions a locomotive can haul as much, or even more, load than it can start. The booster consists of a pair of independent engines coupled to the trailer wheels of locomotives, thus utilizing weight not otherwise used for traction, in starting and quickly accelerating trains and in reducing violent shocks in starting, which are so hard on draft gear and the temper of passengers. As its power cuts out automatically at a speed of 10 miles per hour, it uses steam at low speeds when the boiler can over-supply the main cylinders. It is, therefore, an indirect but valuable fuel saver through increased locomotive capacity. The booster can add about 10% to the starting drawbar pull of heavy freight and as much as 25 to 35% to the starting drawbar pull of lighter passenger locomotives.

Feed-Water Purifiers.—After selecting the softest natural feed waters, such others as may have to be used should be chemically treated to reduce objectionable impurities to a minimum. A conservative estimate of the effect of scale $\frac{1}{16}$ in. thick on flues is to increase fuel consumption 10 per cent. The Hungarian State Railroads on 3 000 locomotives use a mechanical feed-water purifier mounted on top of the boiler. The water on entering the purifier is subjected to full boiler pressure and temperature, and deposits its scale in and on this adjunct to the boiler instead of in the boiler and on the flues. With reduction of scale there is a direct saving in fuel consumption, while a reduction in frequency of boiler washings saves considerable time and fuel.

Without the purifier, locomotives were washed on an average every 5 days; with the purifier, the required washing was once every 54 days.

Lubrication.—All journal bearings must be carefully lubricated to reduce friction; so must the center and side-bearings of cars, the friction of which prevents the adjustment of trucks on entering and leaving curves and thereby, in the aggregate, causes a heavy increase in the resistance to traction that the locomotive must overcome.

Wear on all wheels of locomotives, tenders, and cars must be watched. If the treads are worn hollow or flanges worn vertical, the areas in contact with the rails when cars are oscillating or rounding curves will be increased and the friction correspondingly increased. A heavy freight locomotive, tender, caboose, and sixty freight cars are carried on more than 500 wheels; a slight increase in the friction on a few of them only would, in the aggregate, create a heavy drag on the locomotive.

Flange Lubrication.—Flange lubrication reduces friction between rail and flanges and, therefore, has a substantial effect in reducing fuel consumption. On two roads on which flange lubrication was used, locomotive tires showed average mileages between turnings of 33 000 and 44 000, respectively, compared with 16 000 and 23 000 without such lubrication. Similarly the wear on rails in curves showed a reduction of as high as 87 per cent. On one road of excessive curvature and grade the life of locomotive tires was increased 375% with flange lubrication.

Fuel Specifications.—To insure full heat value the specifications for fuels purchased should cover their value in British thermal units.

Maximum Loads in Vehicles.—Freight cars should be fully loaded as far as may be. The resistance of a train of empty freight cars may run up to 8 lb. per ton; that of cars with average loads to 6 lb. per ton, while that of heavily loaded cars, of total weight of 60 to 70 tons, may be as low as 4 lb. per ton. The load, in other words, should be carried in as few cars as possible.

Reduction of Dead Weight.—As the expenditure of fuel in hauling a ton is the same whether or not it is paying freight, it is evident that the smaller the percentage of non-paying or dead weight to total weight moved, the smaller will be the cost of hauling the paying freight.

The United States Railroad Administration's 50-ton, single-sheathed box car weighs 47 200 lb.; the American Railway Association's 50-ton box-car design weighs 42 400 lb. Thus, the excess weight of the United States Railroad Administration's car is 4 800 lb., or 11.3 per cent.

Based on 1923 data, the saving in fuel by eliminating this excess weight, is $9.77 per car per year, or $4.10 per ton, which, capitalized at 5%, shows that an added initial expense of $82 in building a car is justified to reduce its weight 1 ton.

As far as practicable all weight in a locomotive above what is needed for friction to develop traction should be eliminated.

Boiler design to suit the class of service and the character of the fuel requires considerable flexibility in this principle.

Stimulation of Interest and Co-Operation in Saving Fuel.—Assuming that locomotives are properly maintained, in order to obtain the best results from burning fuel it is necessary to inspire the interest and secure the co-operation of the men on the foot-boards of 65 000 traveling power plants. How these aids are attained will appear from a brief of the practice on a large system covering many States and operated under the most varied topographical and climatic conditions:

1.—In addition to the inspection at each terminal of engines on their arrival and again before departure to insure the correction of all defects before the engine begins its trip, very thorough monthly inspections are made of all parts of the engines, boiler and appliances, draft arrangements, etc.

2.—Classified statistics supply a complete history of operation. To be of most use they are issued immediately after the occurrences they record:

(*a*) A fuel bureau receives the report of all train and locomotive movements within two days. Ton-miles, fuel consumed per 1 000 ton-miles, tons per train for each individual locomotive and each individual engineer and fireman are then computed, and the results put into the superintendent's hands three to six days after the movement, so that shortcomings can be detected and quickly corrected.

(*b*) Monthly statements of individual performance of engineers, firemen, and locomotives are displayed on bulletin boards.

(*c*) A sheet recapitulating results by divisions is issued monthly.

3.—On each division a fuel committee composed of four engineers, four firemen, one conductor and one brakeman, serves for six months and holds meetings bi-monthly, the superintendent acting as chairman. The meetings are well advertised and are attended by the superintendent's staff and employees from all related departments, who offer suggestions freely. Experts on operating methods and appliances deliver addresses. Motion pictures illustrating actual road conditions are exhibited. Minutes of meetings are widely distributed and published in an employees' magazine.

4.—To create emulation between divisions, a red silk banner is awarded quarterly to divisions showing the greatest improvement in the previous year.

5.—Gold-plated cap badges are awarded quarterly on each division to the engineer and fireman showing the best fuel record in through and local freight and passenger service.

6.—Each superintendent publishes the names of five engineers and five firemen having the best fuel records for the month in through and local freight, passenger, and yard service on a roll of honor, which is posted in roundhouses and printed in an employees' magazine. A letter of commendation is sent to each man whose name appears on the roll.

7.—The company sends yearly, at its expense, thirty-eight men, consisting of an engineer and a fireman from each division with the best fuel records, as its representatives to the Annual Convention of the International Railway Fuel Association.

As a result of the policy described and of many fuel-saving devices, the railroad moved 50% more gross ton-miles per pound of fuel in 1924 than in 1913.

V.—Transportation Department

About 20% of all locomotive fuel is consumed when the locomotive is not doing useful work.

(*a*) Avoidable losses include fuel used in firing up, unconsumed fuel drawn from fireboxes, from blowing off and cooling down at ends of runs, and losses incurred while waiting for water, sand, and other supplies on roundhouse tracks. These can be very greatly lessened by reducing the frequency of these occasions, that is, by lengthening locomotive runs. It is not uncommon now to run freight locomotives over two or three freight divisions, and passenger locomotives over four before cooling them. Tables 1 and 2 give some examples of modern practice.

TABLE 1.—Passenger Runs of 575 Miles and More.

Road.	Limits of run.	Mileage.
Southern Pacific	Los Angeles, Calif., to El Paso, Tex.	815
Missouri, Kansas and Texas	Parsons, Kans., to San Antonio, Tex.	678
Union Pacific	Kansas City, Kans., to Denver, Colo.	640
Southern Pacific	San Antonio to El Paso, Tex.	620
Atchison, Topeka and Santa Fe.	Winslow, Ariz., to Los Angeles, Calif.	602
Union Pacific	Denver, Colo., to Ogden, Utah	577
Southern Pacific	New Orleans, La., to San Antonio, Tex.	575

Four locomotives only are used by the Southern Pacific to haul passenger trains from New Orleans to San Francisco, 2 490 miles.

TABLE 2.—Freight Runs of 350 Miles and More.

Road.	Limits of run.	Mileage.
Southern Pacific	El Paso to Del Rio, Tex.	453
Southern Pacific	Sparks to Carlin, Nev.	387
Southern Pacific	Houston, Tex., to Algiers, La.	362
Southern Pacific	San Antonio to Fort Worth, Tex.	352

(*b*) Good despatching will reduce the number of needless stops, and careful planning will avoid fuel waste from locomotives standing in sidings because of poor meeting points, and from idle time at terminals waiting for trains.

To stop a freight train of 66 cars weighing with its locomotive and tender 6 204 000 lb. and moving at a speed of 40 miles per hour, and to regain that speed requires a consumption of 380 lb. of coal.

(*c*) The economy of moving tonnage in as few cars and trains as possible and of reducing empty mileage is obvious.

Trend of Current and Future Economic Development

Much idle time and fuel can be saved by carefully designed engine terminal facilities, such as hot-water boiler-washing plants, well-located supply tracks, etc., and above all ample shops and modern tools to make repairs quickly. Additional shops and tools provided at El Paso on the Southern Pacific Lines have reduced the average time in shops of locomotives 25%, the effect of which is to add 33% to the number of locomotives assigned to that Division. On a division operated with Consolidation locomotives where water is exceptionally good, 16 000 lb. of fuel is saved per locomotive per annum by the installation of a hot-water boiler-washing plant. Such improved facilities, while requiring large capital outlay, will increase the productive time of locomotives.

The burning of fuel in large terminals and shops should be centralized as far as practicable in order to eliminate machinery starting and stopping losses. Through free use of individual electric motors on large tools and groups of small tools the waste of running long lines of shafting and of operating tools needlessly when only one or two on the line are used, can be eliminated and substantial economies can be effected in the 16 000 000 tons of fuel consumed on railroads in shops, stations, etc. In a large railroad shop 20% of the power was saved by eliminating steam-pipe losses and 13% more by abandoning long lines of shafting and many belts through substituting electric for steam power. The changes represented a saving of $120 000 per year.

In locations where electrical energy can be purchased at lower cost than it can be produced by the railroad company, opportunities for substantial fuel savings are presented.

It is encouraging that the improvement in the work obtained from a pound of fuel is constant, but it is disappointing to reflect that European engineers are responsible for most of the improvements now in use on American locomotives. This is the case with the improved outside valve gear, superheaters and feed-water heaters, some details of which, however, have been designed by American engineers, but nevertheless it is mortifying to admit that the principles underlying these devices were not first used in the United States. The reason of course is that heretofore fuel has been so cheap and easily obtained that there was little inducement to pay much attention to its conservation; conditions have radically changed in the last few years, however.

The two principles affecting most profoundly the efficiency of stationary steam engines are compounding and condensing. Compounding alone may increase the efficiency of an engine 13%, and condensing alone may increase it as much as 30%, that is, condensing alone would increase the efficiency of fuel consumption of locomotives nearly as much as the brick arch, superheater, and feed-water heater combined, which as already shown amounts to 34.5 per cent. Compounding, which was used in the United States at one time much more than at present, will certainly come into use again; so that the combined effect of all the devices described, with compounding and condensing superadded, would be:

Brick arch when used has reduced fuel consumption to.. 91.0%
The superheater when added has reduced it to..... 72.8%

The feed-water heater when added, to	65.5%
Using condensing engine may reduce it to	45.9%
Compounding may reduce it to	39.9%

European railroad engineers are fully alive to the advantages of using a condensing engine on the locomotive, as evidenced by descriptions that have appeared recently in the technical press.

Turbine Locomotives.—The Swiss Federal Railways* is testing a 10-wheel type locomotive, with a superheater, driven by a condensing steam turbine, located on locomotive frames in front of the smokebox. It is claimed that tests thus far show reduction in fuel consumption of 25% compared with compound locomotives of the usual construction, and very smooth running at high speeds on account of the reduction of heavy reciprocating parts.

The Swedish State Railway has also built a turbine locomotive.† It is claimed that this locomotive, known as a Ljungstrom locomotive, shows a fuel consumption of about 50% of that of a Pacific type locomotive, which it replaced.

The London and Northwestern Railroad has built an experimental locomotive driven by a condensing turbine which operates a generator, and the power is applied to the driving wheels through four electric motors of 275 h.p. each.

Electric Locomotives.—Where electric current can be generated from water power, trains can be moved very cheaply, but where the current is generated in a steam plant the advantages are much diminished. In eight large steam-electric plants studied in 1919 by the United States Geological Survey,‡ 12.2% of the energy in coal is converted into electric energy; transmitting this electric energy to the motors of an electric locomotive reduces the available power to 9.9% and the output is further reduced in the motors to 8.4% of the total original energy in the coal. The corresponding efficiency of a modern steam locomotive with arches, superheater, and feed-water heater is 8.1% under favorable conditions. While under existing conditions the advantage in favor of the electric locomotive may be more than that indicated, the spread is hardly enough to tempt capital to assume the expenses of interest, depreciation, tax, and maintenance that would have to be incurred in changing from steam power to electricity generated in a steam plant. The soundness of this conclusion was demonstrated by studies made of the Sierra Nevada and other heavy grades on the Southern Pacific, where trains are lifted as high as 6 854 ft. in 86 miles. Assuming the current to be generated in a steam station, the interest, taxes, and depreciation on additional net plant required were found to be more than three times as great as the estimated savings to be obtained from electric operations.

Other considerations, such as smoke prevention and the increased capacity on heavy grades, may influence the problem, but the speaker recalls no instance of a change being made solely to save fuel where a steam-generated current was used. The steam locomotive is by no means as obsolescent as its

* *Railway Review*, April 16, 1921.

† *Loc. cit.*, August 12, 1922.

‡ *Professional Paper No. 123*, U. S. Geological Survey.

critics contend. For example, a fuel consumption of 100 lb. per 1 000 gross ton-miles by electric locomotives is given* as applicable "to conditions universally obtaining on regular profiles." Data published by the Bureau of Railway Economics in September, 1921, show that the fuel consumption on 24 000 selected miles of steam railroad averaged but slightly more than 100 lb. per 1 000 ton-miles. Embraced in this mileage were the New York Central, Illinois Central, Chesapeake and Ohio and St. Louis Southwestern Railroads. On 3 142 miles, or 60% of Southern Pacific main-line mileage, the fuel consumption in the same month was approximately 100 lb., while on the Salt Lake Division, 543 miles, the fuel record in October, 1921, averaged only 91 lb. per 1 000 gross ton-miles, for all locomotives. During the entire month of October, 1924, sixty-two Southern Pacific freight engineers held records of having moved 1 000 gross ton-miles with a fuel consumption running between 48 and 59 lb. per 1 000 ton-miles, under "conditions universally obtaining on regular profiles," or but little more than one-half of what was considered a reasonable fuel consumption for electrically moved trains.

These are every-day performances; in the case of the Swedish experimental locomotive, and in records of electrically operated trains, however, the data relate either to experimental runs or to performances under exceptional conditions.

The performance of the modern steam locomotive in every-day service without favorable stage setting is shown in the records of some American roads. On one of them, 26 superheated Consolidation locomotives showed in daily service on a run with long grades of 21 ft. per mile consumptions of coal ranging from 55.8 to 71.7 lb. per 1 000 gross ton-miles, with an average of 63.5 lb. Still more creditable to the steam locomotives and the men who drive them are the records of individual runners. Engineer A in two trips with trains of 2 809 tons consumed 48.7 lb. per 1 000 gross ton-miles; Engineer P in eight trips with trains of 2 863 tons consumed 58.2 lb.; Engineer R in fourteen trips with trains of 2 411 tons consumed 58.3 lb.

Internal Combustion Engines.—These engines vary widely in thermal efficiency and weights per unit, as follows:

	Weight per brake horse-power, in pounds.	Percentage of brake thermal efficiency.
Automobiles	15	19.0
Diesel four-cycle	370	35.0
Diesel two-cycle	250	30.0
Airplanes	1.04	...

The use of the automobile engine, except perhaps for short runs under exceptional conditions with light vehicles, is prohibitive on railroads, because although it is two and one-third times as efficient as the steam locomotive the cost of its fuel is ten times as great.

The Diesel engine, however, shows the highest thermal efficiency of any known engine. As compared with the most modern locomotive, which transforms only about 8.1% of the heat energy of fuel into work, the Diesel engine

* *Journal*, Am. Inst. Elec. Engrs., March, 1920.

transforms 35%, or more than four times as much. Its fuel (crude oil, commonly called Diesel oil) is not converted into gas as in gasoline engines, but is burned in the cylinder in the form of spray, and the expansive force of the products of combustion provides the motive power. Like the gas engine, however, it cannot start itself, but must use some form of variable speed transmission to start trains; the best way thus far devised consists of electric transmission, but the combined engine and generator plants have proved so heavy as to bar their use for heavy traction. Because of its high thermal efficiency, the Diesel engine offers opportunity to make great savings, and its future is very hopeful. A locomotive of this type now being built for the Southern Pacific Lines by the Baldwin Locomotive Works seems to have overcome these handicaps and will soon be ready for trial.

The designs of an Italian Diesel locomotive show the following:

Weight in operation, approximately..... 117 tons
Tractive effort at 18½ miles per hour..... 19 840 lb.

The locomotive is started by highly compressed air stored in tanks and fed to cylinders at the front and rear, and when sufficient speed has been attained to start the Diesel engines, the compressed air is cut off. The air tanks are recharged by a connection with the main engines. The estimated fuel saving over a steam locomotive is 66⅔ per cent.

This design shows progress in adapting the Diesel engines to locomotives of serviceable commercial sizes, particularly in solving the problem of weight, as the weight of a steam locomotive and tender to develop about 20 000 lb. of tractive effort is 150 tons.

The hope of the railroad executive for conserving fuel lies in:

1.—Substituting hydro-electric power for steam, as the best steam locomotives can now fully equal the efficiency of electric locomotives using current generated in steam power stations.

2.—Substituting compound condensing engines for the simple engines now used. From progress made in Europe, the solution of this problem appears encouraging.

3.—The discovery of a cheap, high-gravity fuel that can be used in some engine of the type used in automobiles and airplanes.

4.—Reduction of the weights of Diesel engines sufficiently to permit their use as locomotive engines and the development of a satisfactory variable speed transmission which will weigh much less than an electric generator and motor.

A Diesel electric locomotive built in Germany for the Russian Government shows an over-all efficiency between 21 and 27.4 per cent. A steam locomotive tested at the same laboratory two days later averaged a total efficiency from 7.6 to 8.67 per cent. The fuel consumption of the Diesel electric locomotive was about one-third that of the steam locomotive.

In a special report published in 1923, the National Industrial Conference Board appointed a committee to determine among other things:

1.—Do the industries in the United States need more or fewer engineers than the number now being graduated from engineering schools and colleges?

2.—What kind of men do the industries require from the engineering schools and colleges, and what should be the nature of their education?

The report states:

"The expansion of industry has been accompanied by vastly increased complexity of industrial operations, and the grouping of greater numbers of workers in corporate units has placed upon employers an increased social responsibility toward their employees and toward the life and affairs of the community. All of these changes have created problems of human, social and political relationships in which industry and society as a whole have become increasingly dependent upon trained technical and administrative leaders."

Solutions to these problems have been sought by railroad executives in the establishment of pensions for superannuated and incapacitated workers; in hospital departments, to furnish hospital service on the payment of nominal fees; by the establishment of group life insurance plans whereby employees, regardless of age and without physical examination, receive the benefits of life insurance at approximately one-third the cost of the current commercial rates; and by the establishment of rest and reading rooms at terminals where no opportunities exist for relaxation after working hours.

Continuing the report says: "Of the 41 600 000 persons who were gainfully employed in 1920, according to the United States Census for that year, less than 4% planned the activities and directed the energies of the whole working force." The same census figures show that since 1870 the number of administrators, supervisors, and technical experts has rapidly increased. In 1870, the number of persons engaged in administration and supervision was 170 000, or 1.25% of those gainfully occupied. In 1890, the corresponding data were 450 000, or 1.74%; in 1920, 1 510 000, or 3.6 per cent.

An examination of the personal records of the Chairmen and Presidents of the railroads of the United States shows that in 1922, of 32 Chairmen, 11, or 34%, had risen from the Engineering Department, and of 171 Presidents, 33, or 19%, had risen from the ranks of engineers. Based as they are on data taken from census reports, the conclusions of the National Industrial Conference Board show increasing demands for the services of trained men, and furnish the most reliable and valuable information obtainable on the matters under consideration.

As to schools, the report says:

"It is the business of the schools to train young men into fertile and exact thinkers, guided by common sense, who have a thorough knowledge of natural laws and of the means for utilizing natural forces for the advantage of men and the advancement of civilization. In other words, it is the business of engineering schools to produce, not finished engineers, but young men with a great capacity for becoming engineers, the goal being attained by the graduates only after years of development in the school of life."

Although a good technical expert may not develop into a good executive, nevertheless successful administrators should have certain characteristics, such as, a good grasp of the fundamentals of science; the ability to think logically and quantitatively; exactness of method and power of analysis; the habit of looking forward; sound economic theories; an unlimited capacity to

learn; pronounced firmness combined with high sense of fairness and charity needed to control men; and the ability to write and speak clearly and correctly.

F. B. Jewett, Vice-President of the American Telephone and Telegraph Company and President of the Bell Telephone Laboratories, Incorporated, expresses these views:

"The industry which I am connected with is a highly technical one which is based on physics and chemistry and mathematics; but so are many of the big industries in our country and the more I see of them the more convinced do I become that the directors of these industries in the future are going to be drawn more and more from men who have a thorough grounding in the fundamentals on which the industries are based. In the old days it was not so, but each day we go on now, it becomes more clearly apparent that because the industries are technical, because they are based on the fundamental science, they must be guided by men who have a thorough appreciation of the fundamentals because business is hardly more than mixing the dollar or cents with physics and chemistry and mathematics. Since engineering schools are the place where we expect to turn out men who are going to guide technical industries, we should turn out men who know the principles of the fundamental sciences; who know the method of combining fundamental sciences with the dollar and cents proposition and know English in a way to enable them to express clearly what they know, so that others may profit by it, because it does none of us very much good to be ever so wise if we cannot express our ideas to others.

"It seems to me that if the engineering schools of the future are going to perform their function for the industries they have got to get closer to the proposition of teaching and really inculcating the fundamentals. Let the matter of trying to make executives go, if you will. The men of executive ability will come to the fore in the general run of things, I think, provided the Lord gave them the right human traits and provided they have a thorough grounding in the fundamentals."

E. M. Herr, President of the Westinghouse Electric and Manufacturing Company, says:

"I have been very much impressed with the discussion and especially by the points brought out by the last speaker. I heartily endorse his view of the importance of the fundamentals and of the idea of patient plodding in the minds of men who are going into industry. There is no royal road, to my mind, to a place of commanding importance in industry, or in any other business, and I do not believe that it is the function of educational institutions to try to teach young men to become captains of industry and administrators, or occupy very great and important executive positions."

* * * * * * * *

"While there is general agreement on this view that one of the leading essentials in education in relation to industry is an adequate training in and knowledge of fundamentals, there is wide variation in the meaning of the term 'fundamentals.' From the point of view of the industrialist, the term 'fundamentals' means a general groundwork of useful knowledge but, more especially, a training in the power to use this knowledge in effective thought and action.

"The fundamentals of engineering training may be stated as follows:

(*a*) Mathematics;

(*b*) The important principles of physics (mechanics, heat, light, sound, electricity, magnetism), chemistry, biology and geology, the interrelations of natural phenomena and the application of these principles to practical problems;

(*c*) The principles of economics and their application to industry and commerce;
(*d*) The principles that govern the relations between people, not only as applied to managers and men, but also as applied to governments and society;
(*e*) The history of nations;
(*f*) The art of clear and correct expression in speaking, writing, and drawing.

"The relative emphasis to be placed on each of these fundamentals is a matter to be determined for each engineering course."

In emphasizing the importance of training, one must studiously avoid withering the aspirations and stifling the ambition of the large numbers of men in railroad and industrial service who have not had the benefit of overmuch school or any college preparation. These men outnumber vastly the high school and college men, and to their credit be it said that the 65% of Chairmen and 81% of Presidents remaining after taking account of those who have risen from the ranks of engineers have been drawn largely from the men who have had none of the benefits of higher education. Without mentioning them, the names of a number of the ablest and most distinguished railroad Chairmen and Presidents in the United States, who have by sheer ability and pluck risen from lowly ranks and have actually built their own careers and builded admirably well, suggest themselves.

Again quoting from the report to the National Industrial Conference Board:

"Sympathetic guidance of both the college man and the non-college man presupposes a careful evaluation of the work of all employees and assurance to them that talent and effective work will be known to and appreciated by the management. Educators report a growing feeling among undergraduates that in most large corporations a young employee often is lost in a department and for many months may not come under the observation of the leading men of the organization. A large public utility company, the two largest manufacturers of electrical apparatus, and a few other large corporations which have unusual and enlightened personnel departments, in many cases are getting the pick of the young talent, because of their attention to this problem."

"These are some of the ways in which industry can supplement the work of the educators," and profiting by their example thus can the present generation help those who are to "carry on" when it shall have passed.

Paper No. 1584

MULTIPLE-ARCH DAM AT GEM LAKE ON RUSH CREEK, CALIFORNIA*

By Fred O. Dolson† and Walter L. Huber,‡ Members, Am. Soc. C. E.

With Discussion by Messrs. J. Y. Jewett, L. R. Jorgensen, Walter H. Wheeler, C. A. P. Turner, Thomas H. Wiggin, C. H. Howell, E. W. Lane, E. J. Waugh, Alfred D. Flinn, Luigi Luiggi, Thaddeus Merriman, M. M. O'Shaughnessy, J. B. Lippincott, Oren Reed, B. F. Jakobsen, J. D. Galloway, I. Oesterblom, B. C. Collier, Fred A. Noetzli, F. W. Scheidenhelm, Charles W. Comstock, George W. Howson, and Fred O. Dolson and Walter L. Huber.

Synopsis

This paper is submitted for the purpose of calling the attention of engineers to the necessity of giving serious consideration to the action of frost when designing dams for use in cold climates. The writers believe deterioration from frost action will occur in any thin concrete structure subjected to water pressure and extreme cold unless the concrete can be made 100% water-proof (or water-tight).

The results of frost action, therefore, have been pointed out in this paper, together with the expensive repairs necessary to safeguard the structure, and it is hoped the discussion will develop some positive and permanent method of water-proofing concrete.

Introduction

Much has been written in recent years concerning multiple-arch dams, but the writers believe that all the story is not yet told, and it is with the

* Presented at the meeting of October 7, 1925.

† Vice-Pres. and Asst. Gen. Mgr., Southern Sierras Power Co., Riverside, Calif.

‡ Cons. Engr., San Francisco, Calif.

hope of placing before the Engineering Profession another valuable chapter that this contribution is offered. Much of the material heretofore presented has dealt wholly, or almost entirely, with mathematical analyses. It is not intended to attempt an addition to the store of material available along these lines. Indeed, a mathematical analysis and a complete description of the structure which is the subject of this paper has already appeared in the publications of the Society.*

Gem Dam was built in 1915 and 1916, and at the time embodied all the best practice in the design of multiple-arch dams, as is evidenced by its designer, L. R. Jorgensen, M. Am. Soc. C. E., having been awarded the Norman Medal by the Society in 1917 for his paper entitled, "Multiple-Arch Dams on Rush Creek, California".* Eight years of subsequent operation of this structure, during which time the concrete has partly disintegrated by freezing, has afforded opportunities for observations and has necessitated remedial measures which, it is believed, cannot fail to be of interest.

Descriptions of engineering structures which have failed to function as intended are often very instructive. It is hoped this one will prove to be as interesting to those members of the profession who are concerned with similar structures as it has been to the several engineers who have had to do with remedial methods.

Selection of Multiple-Arch Type

Gem Dam, on the head-waters of Rush Creek in Mono County, California, is well up on the eastern slope of the Sierra Nevada Mountains at an elevation of 9 050 ft. (water-surface level) and in one of the most remote localities in the West. All materials necessary for its construction except lumber, which could be cut locally, and rock, must be moved long distances and under difficult conditions. Cement had to be shipped from the place of manufacture by broad-gauge railroad 336 miles, transhipped to a narrow-gauge railroad, and hauled 84 miles farther; then hauled over a sandy desert road, using engines or motor trucks of the caterpillar type, for 70 miles, to the power-house below the dam. Here, it was reloaded on tram cars and raised more than 1 250 ft. vertically on a 4 826-ft. tramway to Agnew Lake, where it was rehandled, loaded on barges, and towed across the lake to be again rehandled and raised an additional height of 550 ft. by another tramway, being finally placed on the dam site at a total cost, even under 1915 conditions, of $7.50 per bbl. In the high altitude of this site, the season during which construction work can be advantageously conducted is necessarily short, often only four months and seldom longer than five months.

The dam site is one of exposed, hard, blue limestone and igneous granite, still showing in many places the polish placed on it in the Glacial Age by the glacier which formerly extended down from the higher Sierra. No earth and very little sand is found in this locality.

Physical conditions governing the original construction of Gem Dam had much to do with the selection of the multiple-arch type. Materials for an

* *Transactions*, Am. Soc. C. E., Vol. LXXXI (1917), p. 850.

earth dam were not available. A masonry dam was thought, at the time, to have certain advantages over a rock-fill type. Because of the excessive cost of materials, the quantities required for a masonry dam of the gravity type had to be avoided. These considerations led to the selection of the multiple-arch type.

Description

Gem Dam was constructed in 1915 and 1916 at the outlet of Lower Gem Lake. The reservoir created by it has a storage capacity of 17 216 acre-ft., and is supplied by the run-off from a water-shed of 21.3 sq. miles, ranging in elevation from 9 000 ft. at the dam to 13 090 ft. at Mt. Lyell. The dam is composed of sixteen complete arches, of 40-ft. span, between centers of buttresses, and two fractional arches at the ends. The length at the crest is 688 ft. The maximum height of any individual arch is 84 ft., and the vertical distance from the crest to the deepest point in the foundation is 112 ft.

The arches vary in thickness from 1.0 ft. at the crest to 3.95 ft. at the deepest point, and the up-stream face is inclined at an angle of 50° from the horizontal. The buttresses vary in thickness from 1.85 ft. at their tops to 4.25 ft. at the deepest point, and are strengthened by counterforts, varying in total width from 4.5 ft. at their tops, which are 15 ft. below the crest of the dam, to 11.0 ft. at the deepest point. Two sets of double, horizontal, braced 12 by 30-in. struts extend between the buttresses, one set 15 ft. and one set 45 ft. below the crest. Spillway openings, which can be fitted with stop planks, have been left near the crest of the dam in the two southern arches, the five openings, 6 ft. long by 2 ft. deep, in the end arch being at Elevation 9 050, and the eight openings, 6 ft. long by 2 ft. deep, in the next arch at Elevation 9 048. A steel pipe line leads directly from the dam to the power-house, where a static head of 1 807 ft. is obtained.

This general description, together with the plans, Figs. 1, 2, and 3, and the photographic views, Figs. 4, 5, and 6, should give the reader a fair idea of the structure as it existed from its completion in 1916 until its repair in 1924. A more complete description, including details of reinforcement and an analysis of stresses, is given in Mr. Jorgensen's paper, previously mentioned. A review of this analysis will show that the stresses are within the limits prescribed by good engineering practice and that the design is more conservative than that of other multiple-arch dams which have been constructed to greater heights.

History of Operation

During the eight years of operation of the structure, very few cracks occurred in it. A horizontal crack developed in each of the arches immediately below its crest, due undoubtedly to the fact that the deflection of the walk along the crest, which acted as an arch between the tops of the buttresses, was less than the deflection of the thinner arches of the dam immediately below. This crack introduced no element of weakness and, because of its location and

its very slight width, was not evident except to the critical observer. Its existence simply permitted the arches of the dam to resist all water pressure unaided, a function for which they were designed.

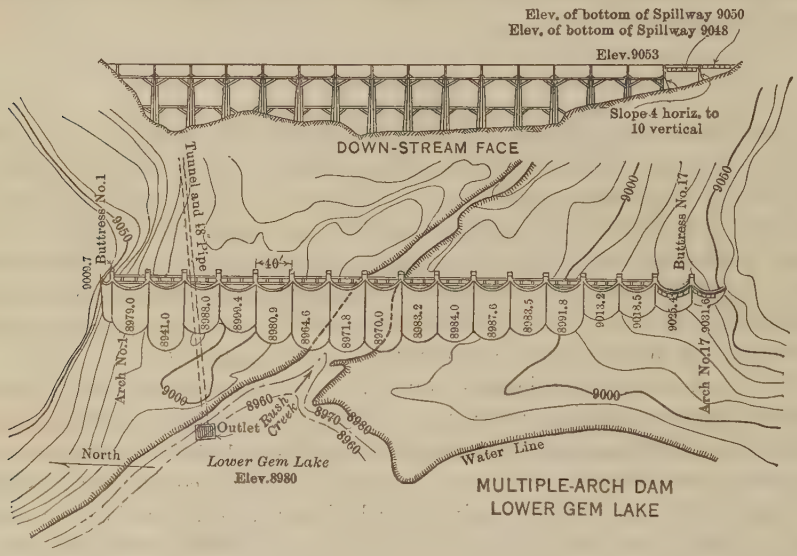

FIG. 1.

Very small diagonal cracks developed near the up-stream toes of three of the buttresses. They were similar to cracks which have developed in the buttresses of practically all the multiple-arch dams which have been constructed to date. The usual practice has been to provide but little reinforcement in buttresses or to omit it. It is believed that the introduction of a comparatively small amount of reinforcement would have eliminated these cracks in every instance.

Gem Dam has withstood some rather severe tests. In September, 1918, a very heavy rain on the upper water-shed occurred when the spillways were partly blocked with flash-boards, and before the flash-boards could be removed, the entire structure had been overtopped to a depth of 4 in. This overtopping lasted for 8 hours, but not to the maximum depth throughout. Although it was not designed as an overflow dam, no damage resulted.

When the structure was constructed, the up-stream faces of the arches of Gem Dam were covered with a 1 : 2 plaster coat of cement mortar, applied with a cement gun. This coat varied in thickness from $\frac{1}{4}$ in. at the top to $\frac{3}{4}$ in. at the bottom.

At first, the leakage was very small. Mr. Jorgensen* thus describes it:

"Some of the arches on the Gem Lake Dam are absolutely tight, some of them sweat in places, and a few drip in places. A few small springs have formed behind the dam, and a trickle of water comes under one arch; but, all told, the total leakage is very small."

Fig. 2.—Water Face of Gem Dam After Completion of Gunite Coat. Note Operation of Spillway with Stop Planks in Place.

It remained small for two years after the completion of the dam and the filling of the reservoir, and during this time no change in the structure was apparent. During the third year some leakage developed and a white deposit was noticeable on the rear faces of the arches. At first, this condition was not considered serious, as a small amount of leakage through a concrete structure is not necessarily a cause for alarm. After chemical analyses, it was concluded that the white deposit was laitance which was being washed out of construction joints.

During the next two years serious disintegration started on the face of the dam, apparently due to the concrete freezing in thin layers on the face and disintegrating by frost action. This action which was slow at first, increased very rapidly with each additional year of age. It was originally believed that the damage had resulted from ice which formed on the surface of the water in the reservoir to a thickness of 30 or 40 in. This ice adhered to the surface of the dam and, as the water was lowered and the ice thus left overhanging, it would tear loose, presumably taking the gunite coating with it. However, this theory was partly disproved by cutting a hole through the ice near the dam and examining the water face immediately below. It was found that, for 8 or 10 ft. under the reservoir surface, this face was covered with a thin layer of ice, thus proving that the freezing was through the thin concrete section of the dam and that the ice on the surface of the reservoir was not the entire cause of the damage.

It was believed that the condition could be remedied if the water face of the structure could be effectively and permanently water-proofed. A careful and detailed study of possible methods of accomplishing this result was made. This study included laboratory tests by J. Y. Jewett, Assoc. M. Am. Soc. C. E., of twelve brands of water-proofing compounds, all of which failed to meet the requirements of the tests.*

The study of water-proofing compounds led to the selection of the so-called "Ironite" treatment. Before applying this treatment, all concrete that showed any signs of disintegration was chipped from the face of the dam. This proved to be quite a task. In places, the concrete over large areas was chipped to a depth of as much as 8 in. Concrete was very carefully replaced in these areas to insure a good bond, and the ends or corners of such areas were chipped out square in an attempt to preserve arch action. After the application of the "Ironite" treatment, the dam was practically water-tight for a short time. However, the "Ironite" coating soon developed hair-line cracks, probably due to expansion and contraction of the arches, and thereafter, with the return of low temperatures, deterioration began again. It was then apparent that more heroic remedial measures must be adopted.

Condition of Dam in 1924

A careful examination showed the upper portion of all arches, extending down approximately 30 ft. from their tops, to be in perfect condition and undoubtedly as strong as at any time in their history. Likewise, a section

* See p. 737.

of the bottom of each arch was little affected. In the intervening middle belt, the concrete had become a dead, inert material with little strength. All concrete in the buttresses was in perfect condition.

Holes were dug into the affected parts of the arches from their rear faces. A blow from a pick produced no ringing effect. Instead, the effect was such as would result from striking hard clay. The concrete was easily displaced, and, with little effort, holes were dug beyond the surface of the reinforcing steel to depths of approximately 18 in. (see Fig. 7), as far, in fact, as it was believed to be safe to carry such exploration, considering that at the time some water was in storage in the reservoir.

A review of conditions convinced all the engineers who made investigations that the damage was due to water from the reservoir percolating into the concrete and there freezing. Temperatures as low as — 25° Fahr. had been recorded during winter months. A review of records showed that when extremely low temperatures had occurred, the water level, in the natural operation of the reservoir, had always been drawn down 30 ft. or more from the crest of the dam, which accounted for the good condition of the concrete in the upper portion of the arches. The flood stages of Rush Creek, which are due almost entirely to melting snow, occur in May, June, and July; consequently, the reservoir is drawn down before the low temperatures of the following winter occur. The buttresses, not being subjected to water pressure at any point, were unaffected. Those parts of the bottoms of the arches which were but little affected, were undoubtedly protected from extreme low temperatures by a snow blanket drifted against their rear faces. This conclusion is substantiated by a similar experience of The Nevada California Power Company with a simple intake dam on Bishop Creek built of thin sections which were similarly affected by low temperatures until the sections back of the concrete water face were filled with earth.

Because of the developments just described, it becomes of particular interest to inquire into the history and quality of the concrete which was affected. As noted by Mr. Jorgensen,* the arches were of 1 : 2 : 4 concrete, the actual ratio of sand to cement being varied with the size of the aggregates, but in all cases 1½ bbl. of cement per cu. yd. of aggregates were used. The rock was crushed in a gyratory crusher and separated into three sizes by a revolving screen having 1½, ¾, and ¼-in. meshes. The rejects from the screen went into a jaw crusher set to give a maximum size of 2 in. A sand deposit along the shore of Gem Lake was used. Mr. Jorgensen describes the sand, as follows:

"This sand was first pumped, and later shoveled, from the lake, and transported to a storage pile near the mixing plant. This lake sand, which contained 3½% of clay and 1% of dirt, was mixed with the sand from the rock crusher (all particles being less than ¼ in. in diameter) in the proportion of about three-fourths of lake sand to one-fourth of crushed rock sand. This gave a very good combination, both as to strength and water-tightness."

Compression tests on 6-in. cylinder specimens, made as the work progressed, showed an average strength of approximately 900 lb. per sq. in. for crushing

* *Transactions*, Am. Soc. C. E., Vol. LXXXI (1917), p. 879.

FIG. 7.—EXPLORATION IN REAR FACE OF GEM DAM EXPOSING REINFORCEMENT.

at the age of 14 days. Concrete was distributed to the different arches and buttresses with two-wheeled push carts and short chutes with the minimum opportunity for separation.

Before construction was begun, the design was reviewed by the J. G. White Engineering Corporation, and a representative of this Corporation also later reviewed and favorably commented on the work in the field.

Remedial Methods

The conditions described had developed by the spring of 1924. The preceding winter had been one of almost record low precipitation. It was evident that the run-off would not be sufficient to fill the reservoir and that repairs, if carried out during this one field season, could be completed without the loss of any stored water. On the other hand, repairs extending through two seasons might necessitate wasting considerable water and thus result in a financial loss which should be directly added to the cost of repairs. It should be noted that 1 acre-ft. of water stored in this reservoir is capable of producing 1 200 kw-hr.

Serious consideration was given to the problem of providing a rock-fill back of the concrete structure and utilizing the existing concrete arches as the water-tight face of the rock-fill dam to be thus constructed. Although a rock-fill dam, with its ready drainage, is very desirable at a location such as this, two objections to this method of repair were at once evident. The great quantity of rock necessary could not be placed in a single season, possibly not in two seasons, but, even more important, it was hardly probable that such rock-fill could be placed by any practicable methods so that it would not settle away from the concrete arches and allow them to continue to withstand the full pressure of the water until after they had actually failed.

It was finally decided that the best method of repair would be to pour a concrete gravity section back of each of the arches, extending it up to within 30 ft. of their tops. The section adopted is shown in Fig. 8. To have carried the section higher would have required greater quantities than could have been poured in a single field season. The upper 30 ft. of the existing arches and the buttresses supporting them appeared to be in perfect condition and to need no reinforcement. To clear up all doubts concerning the condition of the upper 30 ft. of the existing arches, they were drilled and tested for hardness. Two samples were cut from what appeared to be the poorest sections and were tested for strength in compression. The tests showed results of 1 880 and 2 170 lb. per sq. in., respectively. The normal operation of the reservoir during eight years had not subjected this part of the dam to water pressure during seasons of extremely low temperature, and it is not probable that future operating conditions will require that they be so exposed. It is not improbable that a horizontal crack will develop in the existing arches opposite the top of the gravity section, due to difference in rigidity of the two types, but it is not believed that any serious results will be occasioned. The two types will simply act independently and without serious leakage.

PLAN OF REINFORCEMENT OF GEM LAKE DAM BY ADDITION OF GRAVITY SECTION BACK OF LOWER PORTION OF ARCHES

FIG. 8.

It will be noted that the section added back of the arches is not only heavier than standard profiles of gravity dams of similar height, but that, with the added pressure due to the reservoir being filled 30 ft. above the top of the gravity section, the resultant falls well within the middle third of the base, and the maximum pressure at the down-stream toe does not exceed 5 tons per sq. ft. (70 lb. per sq. in.). This is a very light pressure for the excellent hard rock foundation. In addition to the stability afforded by the gravity section, it is necessarily arched in plan, following the 40-ft. arches of the structure already existing. The section was also carried back to secure an excellent bond against the counterforts of the buttresses. It is not believed that stresses can be induced in the gravity section by pressures on the upper 30 ft. of the dam, because such pressures will be transmitted direct to the buttresses.

Drains of precast porous blocks 12 in. square with 4-in. cores were placed at the up-stream toe of the gravity section, and thus at the base of the rear faces of the arches of the former multiple-arch dam and also along the springing lines of the arches. These drains were connected to 4-in. tile-drains laid on a slope of 1 in 50.

Construction

The gravity section was constructed by Dwight P. Robinson and Company, Inc., E. C. Macy, M. Am. Soc. C. E., being in personal charge. The work was begun in June, 1924, and approximately two months of the short available field season was required for the installation of plant and equipment, consisting of rock crusher, aerial cableway, inclined tramway, bunkers, decking, etc.

The tramway from the power-house at Silver Lake to a boat landing at Agnew Lake, constructed in 1915, and previously mentioned, was again utilized after extensive repairs. This tram was constructed of 36-in. gauge track, and both 25-lb. and 16-lb. rails were used, the total length being 4 826 ft., the maximum grade, 68%, and the vertical rise more than 1 250 ft., with many curves and several trestles. A small flat car, 4½ by 8 ft., was used to carry materials. The ¾-in. steel hauling cable was attached to a single drum hoist driven by a 100-h.p. electric motor. All construction equipment, tools, camp supplies, lumber, and cement, was hauled up this incline; in fact, all material used except sand and rock. The usual load per trip was 5 tons. The maximum load, the jaw of the rock crusher, was 10 tons. The most troublesome load was the motor launch, 30 ft. long with 8-ft. beam, which had to be carried on two flat cars and shifted several times while in transit because of small clearances. In handling regular loads, such as cement, a round trip was ordinarily made in 50 min., including time for loading and unloading.

Material delivered at the boat landing on Agnew Lake was loaded on a barge (18 by 24 ft. by 3 ft. deep; capacity, 400 sacks of cement, or approximately 20 tons) and towed across Agnew Lake by a launch driven by an 8-h.p. motor.

From the upper end of Agnew Lake, a double-track, 36-in. gauge, incline railway was constructed to the concreting plant situated above the south end of Gem Dam. Because of the precipitous rock slopes, it was necessary to

support this tramway on a trestle throughout its length of 1 715 lin. ft. The grades varied from a minimum of 10% to a maximum of 70%, and the total elevation surmounted was almost 600 ft. The tracks were straight with the exception of one curve, having a 40-ft. radius and a 48° deflection angle, located near the top. This tram not only carried the loads from the lower tramway, but also all the rock and sand for concrete. Only the southerly track was used for hauling sand and rock, although the tracks were located so that either could have been used. Sand and rock were hauled in a steel trip car of 4 cu. yd. capacity, which, when loaded, weighed approximately 7 tons. The northerly track, which was used for the transportation of cement, lumber, and camp supplies, was fitted with a small flat car similar to that used on the lower tram. Each car was hauled by a $\frac{3}{4}$-in. steel cable attached to a single drum hoist operated by a 100-h.p. electric motor. The motors were equipped with two speed controllers, a slow starting speed and a hauling speed of 400 ft. per min. The rock car was able to make approximately 4 round trips per hour. It is estimated that 26 428 tons of materials were hauled by this double incline during the short field season.

It was hoped that suitable rock could be found near and above the elevation of the top of Gem Dam, but final examinations showed the most suitable rock available for both the crushed rock aggregate and for making sand, to be a deposit of broken granite located below the dam and across Agnew Lake. Laboratory tests of samples of this rock showed it to be entirely satisfactory. To transport this rock across Agnew Lake, a cableway was constructed from the rock pit to the crushing plant which was at the foot of the upper incline. The rock was excavated and conveyed to the loading bunker by a $1\frac{3}{4}$-cu. yd. Bagley grader operated by a double drum hoist equipped with a 75-h.p. electric motor and $\frac{7}{8}$-in. hauling and haulback lines.

The overhead cableway between the rock pit and the rock-crushing plant required a span between supports of 950 lin. ft., the span between anchors being 1 250 lin. ft. The anchor at the end above the crushing plant comprised a set of four 2-in. eye-bolts grouted in holes drilled in a rock ledge about 300 ft. back of the plant. A single-sheave block was laced by $\frac{3}{4}$-in. wire rope to each of these eye-bolts, and a 4-sheave block was laced to another single-sheave block acting as a thimble for attaching the carrying cable. The 4-sheave block was about 50 ft. from the eye-bolts and was laced continuously through each of these single-sheave blocks with the loose end of the cable clipped back on itself. Whenever an adjustment for height was necessary, this loose end was attached to the hauling line for the cableway car and any slack was taken up by power.

The anchor back of the rock pit consisted of a "deadman" and head-frame of round timbers back-filled over with about 100 tons of rock. The dead end of the cable was clipped around a 36-in. log and carried up through the head-frame, where a 6-sheave block allowed adjustments for height. The hauling hoist was on the mountain side to the rear of the rock-crushing plant and directly under the carrying cable. It was designed to operate the car at a line speed of 500 ft. per min. The haulback hoist was set in the head-frame

Fig. 9.—Partial View of Equipment and Camp, Showing Operation of Inclined Double Tramway, Bunkers, Decking, Etc.

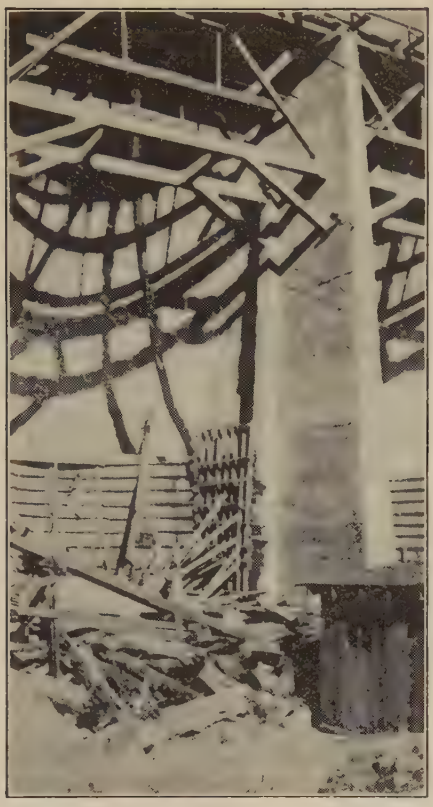

FIG. 10.—FORM WORK FOR ARCHES AND CONCRETE SPOUT FOR CONVEYING CONCRETE FROM OVERHEAD DECK.

FIG. 11.—VIEW OF AGNEW LAKE, SHOWING LANES KEPT OPEN THROUGH ICE FOR PASSAGE OF LAUNCH AND BARGE.

of the rock-pit anchor. The erection of the original carrying cable, which was 2¼ in. in diameter, was a difficult task requiring the laying of the cable across the lake by utilizing the barge and motor, attaching the end at the rock-pit anchor, and pulling it up to position by use of the hauling hoist and rope. The original cable stranded soon after it was put in operation and was replaced by a 1½-in. Langlay, steel-core cable, which was much more easily handled. Pontoons across the lake, constructed by securing in position beneath the carrying cable a number of small logs held in position by ⅜-in. wires, prevented the hauling lines from dropping down in the lake and catching under rocks.

The concrete mixing plant was located above the south end of Gem Dam. From this point a trestle and deck was constructed over the top of the dam to serve as a platform on which to push the concrete in dump cars of the Kopple type to the point of pouring. Fig. 9 is a view of part of the equipment and camp, showing the inclined double tramway, bunkers, decking, etc. The concrete was dumped through platform hoppers into elephant trunk chuting 16 in. in diameter and conveyed to place in the forms. Owing to the use of large aggregate, it was difficult to handle concrete which showed a slump of less than 2½ in. without clogging the chutes, even with the steep slopes used. A concrete inspector made frequent slump tests and attempted to keep all the concrete of such consistency as to show a little less than a 3-in. slump. A cement bag shaker was utilized and 1 sack of cement was recovered from each 58.4 sacks shaken.

A total quantity of 12 004 cu. yd. of concrete was added to the dam and 16 425 bbl. of cement, or 1.368 bbl. per cu. yd. of concrete, were used. The approximate proportions of the mix were 1 part cement, 3 parts sand, 3 parts crushed stone (¼ in. to 1½ in.) and 1.84 parts cobbles. Compressive tests of concrete samples showed an average strength of 2 400 lb. per sq. in. at an age of 28 days, and 3 440 lb. per sq. in. at an age of 3 months.

Weather conditions permitted continuance of the work somewhat longer than usual, and the last concrete was poured on November 15, 1924. Fig. 10 shows the form work for the arches and the concrete spout for conveying concrete from the overhead deck. Fig. 11 is a view of Agnew Lake showing the lane kept open through the ice for the passage of the launch and barge.

Conclusions

To prevent deterioration of concrete subjected to water pressure and extreme low temperatures, it is necessary that impervious concrete be obtained. The slightest penetration of water will be followed by deterioration, further penetration, and further deterioration.

Plaster coats, such as "Ironite", might be satisfactory except for hair-line cracks which will be developed on any thin arch section by movement due both to temperature changes and to loading and unloading the arches.

Under the difficulties imposed at this site and similar sites in very remote high mountain areas, it is doubtful whether, under conditions of the present day, impervious concrete can be obtained. Therefore, structures composed of

thin sections of concrete should be protected from extremely low temperatures. For such localities, the writers believe that a dam of the rock-fill type has many advantages over dams of other types.

ACKNOWLEDGMENT

In addition to the writers, those who reviewed conditions and assisted in planning the reconstruction include Messrs. R. G. Manifold and the late Charles Oscar Poole, M. Am. Soc. C. E., Consulting Engineers, in whose office the plans for reconstruction were made, and C. W. Comstock, M. Am. Soc. C. E. The construction work was under the general charge of E. J. Waugh, M. Am. Soc. C. E., Construction Engineer of The Nevada California Power Company. As previously noted, this work was performed by Dwight P. Robinson and Company, Inc., with E. C. Macy, M. Am. Soc. C. E., in personal charge.

DISCUSSION

J. Y. JEWETT,* Assoc. M. Am. Soc. C. E. (by letter).—In the early summer of 1923, the writer was called on to examine the structure referred to in this paper, and make a report on certain features of concrete construction related thereto. The repairs, involving use of the "Ironite" process, were at that time under way. Later, as mentioned in the paper, he was asked to make some tests of water-proofing materials, with a view to finding a suitable method of treatment for water-proofing the up-stream face of the dam, a brief description of which tests may be of interest.

The first series of these tests was confined principally to bituminous materials. Engineers of the Company felt that the solution of the problem might lie in the use of some substance having the flexible and elastic properties of this type of material, in contrast to rigid materials of the Portland cement mortar type which readily crack and allow the entrance of water under the severe temperature changes of that locality. The main points to be determined were: Durability under the prevailing climatic conditions; resistance to water pressure; bonding with the concrete surface; and penetration into the pores of the concrete under pressure.

Manufacturers of water-proofing materials of this type were asked to furnish samples of products which they could recommend as being especially resistant to the range of temperature involved. The samples received were classed in three groups, as follows:

(*a*) Solid material, to be melted and applied hot.
(*b*) Liquid material, to be applied with a brush as a paint.
(*c*) Material in mastic or putty form, to be applied with a trowel.

For practically all the samples submitted, the use of a light asphaltic paint as a primer coat was prescribed, and this was generally furnished with the sample.

In tests for resistance to water pressure, a pipe apparatus connected with the city system was used, on which a pressure of 55 to 60 lb. per sq. in. was available. The test specimens were 2 in. thick and 5 in. in diameter, coated on top with the material to be tested. These specimens were bolted between plates, with gaskets to make a tight joint, leaving an area, 3 in. in diameter, in the center exposed to water pressure, with provision for catching and measuring any water coming through. To determine absorption under pressure and penetration into the pores of the concrete, specimens 6 in. in diameter and 4 in. high, entirely coated with the material to be tested, were immersed in a closed tank under the same pressure. The effect of variation of temperature was observed by heating to 110° Fahr., and by exposure in cold storage at slightly below 0° Fahr.

All the materials except a light paint in Group (*b*) formed a coating which was water-tight under the pipe-pressure test. The tank apparatus did not prove to be adaptable to the purpose for which it was used on account of the unbalanced condition caused by difference between air in the pores of

* Testing Engr., City of San Diego, San Diego, Calif.

the concrete at atmospheric pressure and the higher pressure maintained in the tank. This produced rupture of the enclosing membrane, and caused it to puff out in small bubbles and pull away from the surface of the concrete. In no case was there any penetration into the pores of the concrete.

Under the conditions prevailing at this dam, application of the materials of Group (*a*) would be difficult. The hot melted material cools very quickly on striking the cold surface of the concrete, and tends to stick to the tool with which it is being applied, and to pull away from the surface in a sheet. The materials of Group (*c*), although possessing spongy, elastic properties, were in general too soft and easily abraded to form a satisfactory coating, and some of them became softer under water than in the air. Under an increase of temperature up to 110° Fahr. a few of the samples remained unchanged, but the general effect was to soften the material, although not sufficiently to cause flow or change of shape. The specimens placed in cold storage were recently removed after one year's continuous exposure, and were practically unchanged in condition, the coatings showing no sign of cracking or peeling. To show the effect of varying conditions of temperature and moisture as existing at the structure, field exposure tests would be needed.

The conclusion is that if material of this type is used, it should be in paint form, of the class included in Group (*b*). Some of the paints of this group are of heavy consistency, about as thick as can be readily handled with a brush, and dry with a hard, smooth, tenacious coating. Among the several samples having these characteristics, a difference in hardness and tenacity under water immersion was noticed. Trial of a combination coating of such a paint over the mastics of Group (*c*) indicated that, while retaining the advantages of the former, some benefit would also accrue from the elastic properties of the latter.

A second series of tests was made on samples of general water-proofing compounds of the type intended to be applied as surface coatings in paint form. These materials, although showing properties which might be useful in certain classes of work, did not develop results under water pressure that would recommend them for the purpose in question. This series included several brands of the so-called water-proof, plastic, Portland cements now on the market. The plasticity of these products is doubtless of benefit as an aid to workability, in some classes of work, but they did not show water-proofing qualities in these tests equal to those of straight Portland cement. A marked feature of these cements was their low strength in compressive tests of concrete, as compared with straight Portland cement.

To the writer, in view of the results outlined, the problem seems to narrow down to a choice between two methods of treatment:

First.—The use of bituminous paint of the type described. This, although an unusual form of treatment for a structure of this kind, gives indications of furnishing an effective water-proof coating at a relatively low cost. If, however, it should need renewal from time to time, as may be the case, the cost would be a continuing item.

Second.—The use of a Portland cement mortar or concrete coating of high density, reinforced against temperature effects. Although the original cement-

gun coating did not prove to be satisfactory, the usual product of this process is well known as a material of high density, and it should be possible to apply such a coating in this case so as to obtain advantage of this feature; or the procedure could be carried a step further, taking the form of a coating of reinforced concrete, similar to that of which the walls of the concrete ships are built. Without entering into discussion of this type of ship in general, it may be noted that they have shown the possibility of concrete construction in thin walls, of high density. As an alternative to the use of Portland cement in this proposed mortar or concrete coating, the use of a quick-hardening, high-strength cement of the newly developed "alumina" type deserves consideration.

With reference to the discussion by the authors of the concrete in the original structure, it was evidently considered that the work was of a good grade of concrete construction, and that the gunite facing could be relied upon for water-tightness. Tests of the concrete, however, as reported* by L. R. Jorgensen, M. Am. Soc. C. E., and as obtained on the specimens taken from the structure in 1924, show a low compressive strength for the mix used. One feature contributing to this, judging from the writer's observation, was the presence in the rock used as aggregate—which was obtained from material near the site of the work—of thin, flat, smooth-surfaced pieces, which would have somewhat the same effect in concrete as mica in a sand mortar. The authors, in describing the new construction, refer to the selection of a more suitable rock at some distance from the dam site.

Experience with this structure indicates that concrete to be used under similar conditions should be of what may be termed a super-excellent grade. This raises the question of the adequacy of the ordinary contract system (with its natural emphasis on speed of operation and profit for the contractor) to meet such a condition. From the point of view of a testing engineer, who, from his study of materials, perhaps realizes more fully than others the possibilities inherent in concrete as a construction material, a more effective method would be to place such work directly in charge of an engineer familiar with the problem and give him a free hand to obtain the results desired. This is subject, of course, to the limitation that there be no waste or needless expense; but it does leave such a man free to devote his energies to obtaining these results, rather than to expend them in more or less futile inspection efforts under the contract system.

L. R. Jorgensen,† M. Am. Soc. C. E. (by letter).—The distintegration of the middle zone of the arches in the Gem Lake Dam, has naturally given great concern to the writer, as he was responsible for the design and construction of this dam nine years ago; he has therefore been seeking earnestly for a true explanation of this rapid deterioration.

As concrete consists simply of rock, sand, cement, and water, the problem is limited to the investigation of these four materials, aside from the mixing and general workmanship. At the time of the construction of the dam and

* "Multiple-Arch Dams on Rush Creek, California", *Transactions*, Am. Soc. C. E., Vol. LXXXI (1917), p. 850.

† Cons. Engr., Constant Angle Arch Dam Co., San Francisco, Calif.

also as late as June, 1923, these materials were analyzed and tested frequently. The following notes on the tests are taken from a report made by the Noble Inspection Bureau (now Abbot A. Hanks, Incorporated, San Francisco, Calif.):

"Water from Gem Lake	Parts per Million
Sulphates (as Na_2SO_4)	None
Chlorides (as NaCl)	2.90
Carbon dioxide (CO_2)	2.20

"As the sulphates, chlorides, and carbon dioxide were present in such a very small amount, it was not necessary to make further analysis in connection with the investigation of deposit on the concrete. This water is unusually pure."

Relative to crushed rock, the report states:

"We [Noble Inspection Bureau] treated the sample of crushed rock to determine its solubility in water. The results indicate that the calcium carbonate deposit on the down-stream surface of the dam does not originate from this rock."

The sand used was found along the shore of the natural Gem Lake, which was lowered about 15 ft. when excavating for the dam foundation. Approximately, one-half this sand required washing in order to eliminate excesses of clay and vegetable matter. Both mortar briquettes and compression specimens were made of the local sand and of standard Ottawa sand, and the local sand was washed whenever it gave results below the standard in compression and below 90% of the standard in tension. Three kinds of sand were used: A semi-silicious, a basaltic, and a granite sand from the rock crusher. The latter was mixed with the sand from the two natural deposits.

The original structure was built by the Duncanson Harrelson Company, of San Francisco, which Company had had large experience in concrete work and built a good structure. The water contents were kept to a minimum for reinforced water-tight concrete. It is true that the crushing strength of the concrete was not quite as high as ordinarily would be expected for the richness of the mix used. There are two reasons for this: First, concrete in reinforced arches which has to be water-tight can not be deposited as dry as required for maximum strength. In a gravity dam where men can work directly on the newly deposited concrete a slump of 3 in. can be used, but for reinforced concrete in forms, where the concrete can only be reached with long-handled tools, a slump of approximately 5 in. must be used to obtain water-tight concrete. Secondly, the shape of the crushed rock was somewhat elongated. The stresses used in the design were conservative, and therefore the structure was never over-stressed due to the water load.

When the dam was first subjected to water pressure it was remarkably tight. The first time the writer observed anything wrong was about three years after completion. A very heavy white deposit consisting of practically pure calcium carbonate was noticed on the down-stream face 30 ft. below the crest. It is almost impossible entirely to avoid this white deposit on the down-stream face of the dam, at least in moist spots, but in this case the deposit was too heavy to be harmless and kept increasing.

The small white deposits often seen on the down-stream face of dams originating merely from the leaching of the free lime in the cement, or from whatever laitance there may be in the construction joints, are harmless, but when these materials have leached out and appear on the down-stream side in the form of calcium carbonate, the process should stop and nothing further should happen. In the case of the Gem Lake Dam the process never stopped; it seems that in the zone subject to water pressure the cement itself broke down during the coldest weather. Where else could the large deposit come from?

The cement had passed the usual test. It might, however, have been slightly underburned without being noticed, causing it to be at the point of unstability when exposed to the severe cold. Under ordinary conditions the concrete undoubtedly would have kept its strength, but under the severe climatic conditions imposed on it in the middle zone, it deteriorated and lost its entire strength.

The deterioration started at the construction joints, as they were naturally the weakest points in the structure, but if the leaching had only been confined to whatever laitance or free lime there might have been in the joints, the process would soon have stopped. Fig. 7 shows clearly that the deterioration of the concrete was not confined to the joints. A zone 30 ft. high, beginning 30 ft. below the crest and extending all the way across the structure, was subject to heavy frost while the water level fluctuated between the two levels. In this zone the concrete is practically uniformly deteriorated, whereas above and below it is still in good condition.

If the sand had been the cause of the poor showing of the concrete, it could be expected that there would have been good and bad spots of the material, as three kinds of sand were used, sometimes washed and sometimes unwashed.

An analysis of the deposit on the Gem Lake Dam shows the following:

	Percentage
Silica (SiO_2)	0.76
Iron (Fe)	0.05
Alumina (Al_2O_3)	0.39
Calcium carbonate ($CaCO_3$)	97.44
Magnesium carbonate ($MgCO_3$)	0.11
Total	98.75

showing that the deposit is practically all calcium carbonate.

Inasmuch as the deposit continued to accumulate, it was due, in the writer's opinion, to the cement breaking down gradually and the lime in the cement being leached out continually. The time of actual breaking down was during the coldest weather.

The Agnew Lake Dam, built of practically the same material on the same stream, but 500 ft. lower in elevation, is still in first-class condition. The water level in this reservoir, however, is not appreciably lowered during the cold season, and snowdrifts protect the down-stream face to a great extent from the extreme cold weather.

Three years ago (1922) the writer acted as Consulting Engineer on a multiple-arch dam then being built in Northern Sweden on the River Luleaa, 50 miles north of the Arctic Circle. Two dams of a design similar to the Gem Lake Dam were constructed at a location where at times the temperature drops to 50° Fahr. below zero. Both dams have been in use for two years; they are being carefully watched for frost action, but so far none has appeared.

These dams are provided with a back-fill of earth on the down-stream side for a short distance up. The back-fill was put in to protect the lower arch portion against the very low temperature and consequent contraction near the footing where the arches are fixed to the rock. The upper portion of the down-stream face is still uncovered and, therefore, open to inspection. The water level fluctuates during the cold season.

On recent designs of multiple-arch dams, the writer has favorably considered arches of 50 ft. span, instead of 40 ft. A greater thickness of arch is necessary, but this should make it possible to keep the construction joints tight, just by careful workmanship, without plastering the up-stream side. When an arch is so thin that heavy frost can penetrate the concrete and cause freezing on the water side below the water level in the reservoir, it can hardly be expected that a plaster face will have a long life; the adhesion is seldom 100%, and reliance for water-tightness therefore should be placed as much as possible in the concrete itself.

Walter H. Wheeler,* M. Am. Soc. C. E. (by letter).—The description of the Gem Lake Dam is interesting, but the disintegration of the concrete in the structure by frost can be readily explained.

In the description of the aggregates two facts are mentioned which would account for the difficulty. One of these facts is that the lake sand used in the concrete contained 3½% of clay and 1% of dirt, and the other that the screenings from the rock crusher were mixed with the lake sand in the proportion of 1:3. Presumably, the blue limestone, referred to as the country rock at the dam site, was used in the concrete without removing the dust which resulted from the crushing operation. It is the writer's experience that concrete made of aggregates which contain clay and dirt will not resist frost action, and also that limestone dust is very detrimental to the durability of concrete, also that concrete made with certain varieties of limestone aggregate will be quickly disintegrated by frost. The writer has observed many examples of the disintegration (by frost) of concrete in which similar aggregates have been used, and also many examples of concrete made with clean durable aggregates, which have resisted the frost under equally trying conditions. He does not hesitate, therefore, to assign at least a part of the trouble on the Gem Lake Dam to the aggregates used in the concrete. If concrete is to be exposed to frost the aggregates must be carefully selected with that possibility in mind.

There may also be other contributory causes which are not so apparent from the published description.

* Designing and Cons. Engr., Minneapolis, Minn.

C. A. P. TURNER,* M. AM. SOC. C. E. (by letter).—This paper should prove of much value to the profession in calling pointed attention to that particular kind of concrete which will not withstand frost action, namely, concrete compounded of sand as fine aggregate containing 3½% of clay and 1% of dirt. The broad conclusion that concrete disintegrates in like manner when made with suitable aggregate is not warranted from this example. Good initial resistance to compression of sample specimens is too often mistaken as a determinant of frost resistance although in no wise related thereto.

For purposes of discussion, the concrete utilized in the construction of dams may be classified as (*a*) structural concrete; and (*b*) mass concrete. Hollow dams (such as the original Gem Lake design), flat slab dams, and the like represent Class (*a*), while the mass concrete of the gravity type present examples of Class (*b*).

That frost disintegration occurs in Class (*a*) concrete because of the relative thinness of the section, but does not occur in Class (*b*) concrete because of its greater thickness, is apparently the deductions of the authors from the single experience described and discussed.

In certain slabs of reinforced concrete dams much thinner than the Gem Lake section and exposed at times to temperatures of 50° below zero, or lower, no material disintegration by frost has occurred in twelve years or more, whereas in some structures of the gravity type with far thicker sections, in which care had not been used to secure clean aggregate, the writer has observed disintegration by frost.

The importance of the question at issue lies in the fact that the structural concrete dam may commonly be safely built at a much lower cost than a dam of the mass concrete type. Many irrigation projects are rendered commercially feasible by using the economic dam structure whereas they would be lacking in feasibility with the more expensive gravity types. The disintegration of mass concrete, or the thinner section of concrete, by frost appears to the writer as one of progressive action which may render even the massive structure unsafe within a period shorter than its expected life. Hence, the need of care in the selection of concrete materials whether in the bridge pier or dam structure exposed to the elements. The additional first cost of washing sand and securing sound aggregate is always small compared to the cost of repairs when proper care has not been exercised.

THOMAS H. WIGGIN,† M. AM. SOC. C. E. (by letter).—There is at present under construction from the writer's designs a multiple-arch dam about 300 ft. long and 33 ft. maximum height, and the subject is, therefore, of great interest to him.

Many concrete structures, including dams, are deteriorating with the aid of moisture and frost and it is generally impossible to fix the cause with certainty. The authors call attention for the first time in a pointed way to the fact that the immersed side of a thin exposed wall of concrete is in the same danger from the formation of ice crystals in its pores under the influence of

* Cons. Engr., Minneapolis, Minn.
† Cons. Engr., New York, N. Y.

cold coming through from the dry side of the structure as the side not immersed of a thick, leaky wall.

Deterioration was expected and occurred in the mortar lining of uncovered steel pipe, but here the exposure was severe as only a thin plate of steel intervened between the outside cold and the saturated mortar lining only 2 in. thick.

Filter roofs, 6 in. or more in thickness, covered with about 2 ft. of earth, are often wet with condensed moisture and sometimes permit thin ice to be formed on the water below, showing that the air which touches them is, at least, as cold as the unfrozen water against a thin dam. The writer has never noticed deterioration in the lower surface of such filters. None of these filters was in a region of extreme cold.

In the United States some concrete stand-pipes have deteriorated outside from leakage and freezing, but the writer does not recall deterioration inside although the concrete was porous and had to be water-proofed on the inside to prevent further damage outside. The French have constructed some of these stand-pipes that seem to have no imperfections from leakage or frost. These stand-pipes, again, are not in semi-Arctic regions; also, there is more or less circulation of water.

The Stony River Dam in West Virginia is a hollow dam of the Ambursen type. It is at an elevation of about 3 000 ft. and experiences very severe winters compared with most places in the East. Ice forms on the inner faces of the hollow. Deterioration has occurred on the water face, although mostly high up in the zone of fluctuating water levels.

The writer has been advising on the repair of a gravity concrete dam. The concrete has deteriorated both on the water face and on the down-stream face. Disintegration down stream is apparently due to leakage and freezing; that up stream, similarly, is apparently due to saturation and freezing. The concrete is about 1:3:5 and rather poor. Several hundred thousand dollars will be expended in repairs. The safety of the dam has not yet been endangered by deterioration. The interior is sound. This is only one of many dams that have shown signs of surface disintegration. Only good stone masonry seems exempt, and that needs repointing in some cases.

It is not agreeable to contemplate that in spite of all care, concrete structures so often fail to endure. The writer started thirty years ago with the feeling that the place for concrete was underground. Unfortunately, stone for stone masonry is not often available at a reasonable price and the advent of concrete was the beginning of the decline in the supply of stone masons. Engineers are often forced to use concrete where its expectation of life may be comparatively limited, or at least doubtful, because stone would cost so much more that the concrete structure could be often renewed at a less total capital cost. "Hope springs eternal" also that vigilance will produce concrete of such quality that it will be among the structures exempt from major deterioration.

Among those who are engaged in research on cement and concrete are some who lay the deterioration of concrete to the use of too little cement. In the Gem Lake Dam only 1.5 bbl. per cu. yd. were used. Perhaps 1.75 or 2 bbl.

would have shown different results. Some old structures with even less cement are still without blemish, it is true, but this may have been due to extraordinarily good sand and proportioning.

The writer chose a multiple-arch dam for the case mentioned at the beginning of his discussion because rock foundation was found near the surface and other conditions made it by considerable the cheapest type, except possibly a slab dam. About 1.6 bbl. of cement per cu. yd. are being used in the piers and 1.75 bbl. in the arch which is only 1 ft. thick. Even with this thickness the stress is only about 150 lb. per sq. in. from water pressure alone and it is still (October, 1925) very low, with scarcely any tension, with extreme conditions of temperature. It is a flexible structure and no joints need slip to provide for temperature changes. It was hoped to make the dam tight by the excellence of the concrete, but in addition a complete water-proofing of asphalted fabric and asphalt, covered with mastic for protection against ice, is to be provided. The circulation of water in the reservoir will be fairly vigorous and the climate is that of the New York region, that is, generally free from prolonged intense cold.

In their struggles to avoid one set of difficulties, human beings are prone to run into others just as serious. Nature will not be altogether circumvented. An earth dam with generous slopes, paved water slope, grassed down-stream slope, masonry core, and well-drained toe comes as near to being a part of the landscape in permanence as can be produced by man, yet it requires a generous masonry spillway for its protection and perhaps fails by overtopping when the record storm for the region occurs. The masonry dam even partly disintegrated may safely withstand overtopping at such a time.

C. H. Howell,* M. Am. Soc. C. E. (by letter).—This paper is an exceedingly instructive one. The writer believes with the authors that "all the story is not yet told" concerning multiple-arch dams; he would also include all flat slab dams.

The smaller volume of concrete contained in these hollow types, as compared with ordinary gravity and arch sections, has often led to their erection at sites utterly unsuited to them. To expose thin concrete slabs or thin arches to high water pressures and low temperatures is inviting ultimate failure. It is a misuse of types of dams which have a definite, although rather limited, use.

Like all innovations, these hollow types of dams have their over-enthusiastic supporters who can see no merit in the older types and strenuously insist on multiple-arch or flat slab designs for every site. The history of the Gem Lake Dam will probably diminish some of this enthusiasm. The writer knows of one other dam, a flat slab structure, which is deteriorating in the same manner as the Gem Lake Dam. Both these dams were erected in climates that are too cold.

E. W. Lane,† M. Am. Soc. C. E. (by letter).—Since many dams of the multiple-arch and Ambursen types have not been seriously affected by frost action, the trouble at the Gem Lake Dam does not seem to be inherent in dams

* Engr., U. S. Bureau of Reclamation, Denver, Colo.

† Lafayette, Ind.

with thin concrete walls. It does serve, however, to emphasize a possible source of weakness, and the necessity of much more than ordinary precautions in the construction of such dams, especially in cold climates.

A few years ago, the writer inspected a large gravity dam in which the concrete was disintegrating in a manner very similar to that at Gem Lake. The dam was constructed by competent engineers, but within a few years the concrete began to disintegrate and, when inspected, had scaled off in places to a depth of as much as 6 in. and could readily be dug with a knife for some distance from the surface, being about as resistant as compact gravel. The writer was informed that the cause of the trouble was the limestone aggregate. This had been brought from a considerable distance, as the local stone was unsuitable. It had passed all the ordinary tests, but an examination to determine the cause of the disintegration had revealed that the limestone was filled with microscopic veins of shale which broke down on exposure to the weather. Had this material been used in a dam with thin sections, it would certainly have necessitated reconstruction.

The fact that the buttresses of the Gem Lake Dam were not affected strongly points to the water as being an element in the cause of disintegration, but this does not prove that it was not the quality of the aggregate that was the primary cause of the difficulty. In his description of the construction of this dam, Mr. Jorgensen* states that, in the lower part, limestone from the outlet tunnel was used for the aggregate. Is it not possible that the limestone aggregate was the cause of the trouble, and that the reason the upper part was not affected was because it was constructed with granite aggregate?

The writer believes that the materials entering into the construction of a multiple-arch or buttressed dam should be subjected to a much more critical examination than for a dam of gravity section. He would suggest subjecting the aggregate and moulded specimens of concrete to a considerable number of alternate freezings and thawings. This should not be difficult with the small mechanical refrigerators which are coming rapidly into use. In northern climates it could be readily done in winter by natural means.

The danger resulting from disintegration of multiple-arch dams was called to the writer's attention by an inspection which he made of a dam of this type in Central New York. This dam (Fig. 12) consisted of three vertical arches supported by buttresses, flanked by an ogee gravity spillway section at one end and a gravity section abutment at the other. The concrete had disintegrated badly in places (Fig. 13), especially at the springing line of the arches and at a crack (probably caused by temperature) which extended down the crown of each of the three arches. The construction joints were also seats of attack. The disintegration was not confined to the arches, but included also the buttresses and the ogee spillway section. The writer understands that this dam has been repaired, but is not aware what method was used.

E. J. Waugh,† M. Am. Soc. C. E. (by letter).—In any discussion involving disintegration in concrete the first question that naturally arises is what was

* *Transactions*, Am. Soc. C. E., Vol. LXXXI (1917), p. 868.

FIG. 12.—MULTIPLE-ARCH DAM IN CENTRAL NEW YORK, DOWN-STREAM FACE, SHOWING DISINTEGRATION.

FIG. 13.—DETAIL OF DOWN-STREAM FACE, MULTIPLE-ARCH DAM (LEFT BAY IN FIG. 12), SHOWING EXTENT OF SPALLING.

the quality of the concrete before deterioration commenced. If the up-stream face had been absolutely water-tight and had remained so, it may be assumed that the original concrete in the Gem Lake Dam would have given satisfactory service, as no deterioration appears in the buttresses. Also, the arches, where not subjected to freezing when filled with water, are not seriously affected as to structural strength, as is evidenced by compressive test samples taken in 1924.

The failure of the gunite coating to absolutely prevent moisture from getting in back of the top skin was the primary cause of the trouble. During the long season of freezing temperatures, extending from September or October to April or May, any moisture admitted would freeze and in expanding would either loosen the material at the face or tend to enlarge the pores throughout the mass. This operation repeated itself each time the weather warmed enough to thaw. After seven winters, slabs of gunite coating of all sizes had been loosened; that this was not due to faulty bond of the gunite is proved in part by the fact that often a thin layer of concrete adhered to the gunite when it was forced loose from the arch.

The quality of the concrete and the character of the bonding at construction joints has a direct bearing on the rapidity of disintegration, but it is doubtful whether any concrete would resist such freezing conditions indefinitely. It is inconceivable that any concrete will prevent the penetration of moisture. With temperatures that will cause ice to form under water on the reservoir face of the wall, any saturation of the wall whatever will cause damage. Either some facing must be provided that will be water-tight to the extent of allowing no moisture to reach the concrete or else the dam should be back-filled or otherwise insulated against cold. In the original construction a water-tight metal up-stream form would be the most satisfactory solution. It could be asphalt dipped, or otherwise treated, so that it would not rust against the concrete and it could be repainted when necessary on the up-stream face and maintained in water-tight condition at comparatively little cost. Such a form could be designed with expansion joints. In this way the concrete in the arches could be kept dry and the full strength would remain so long as the up-stream metal facing were maintained water-tight. It would be impracticable to carry the metal form below the ground line, but at this point it would be a simple matter to fully protect it by back-fill and still leave the structure open for observation.

It is possible that metal is still the best protection for the Gem Lake Dam, but it is much more difficult to place than it would have been in the original construction. Some substance that has the qualities of adhesion and elasticity and can be sprayed or brushed may solve the difficulty; field tests are now being made with certain bituminous compounds to determine the feasibility of their use.

ALFRED D. FLINN,* M. AM. SOC. C. E.—There is danger in over-emphasizing one notable failure. It is creditable to engineers who have knowledge of failures to report them for the benefit of the profession; but it would also

* Secy., United Eng. Society, and Director, Eng. Foundation, New York, N. Y.

be of service if the Society, through a small committee of inquiry, or an existing committee, would set down against this failure the record of the thin concrete dams under as great or even greater exposure that have stood successfully for years. There are many such dams in the United States. The importance of presenting such countervailing information is not slight. Engineering Foundation might be asked to collect the data for the Society.

Dams are among the structures that are supervised by certain States. Some supervising officials are not well informed about the theory or the practice of the construction of dams. Their responsibility is to make sure that structures which they approve do not fail. The cost put on the owner, or the limitations on the engineers in charge of design and construction, are only secondary to the officials.

Endeavors of American engineers to build successful dams at moderate cost are being watched closely by engineers in other countries. Recent correspondence with an Italian engineer indicates that some American experiences have been misinterpreted. He has been strongly opposing the use in his country of any thin dams. American engineers owe it to themselves to answer the questions which have been raised. These questions may be grouped under the heads: Sufficiency of design, suitability of materials, efficiency of construction methods, and adequacy of maintenance.

For the case in hand: What is known about the materials put into the concrete which failed? What were the chemical and physical characters of the water, cement, sand, stone, and gravel? What attention was given to the proper placing and curing of this concrete for the particular purpose and conditions of this dam?

In some instances is not concrete being used with about the degree of intelligence that would use window-weight iron or alloy steel indifferently as materials for tools for cutting metal? In other words, is not concrete too often designed without sufficient regard for the purposes and conditions of the structures into which it is to be put, and with still less discrimination in supervising its mixing, placing, and curing? Concrete for simple foundations, or for structures which will be wholly protected from the weather or active destroying agents, may be different from concrete suitable for thin hydraulic structures under pressure and exposed to severe weather. This fact is so obvious that slowness in carrying it to the necessary limit in practical operations is hard to understand. Probably the tardiness to realize the relation between cause and effect has been due partly to the fact that the results of some wrongdoing in concrete construction do not appear for several years and partly to the fact that the men who design and construct often do not see their structures again and, therefore, do not learn the lessons which develop during years of maintenance. However, notable progress has been made.

In engineering textbooks, reports, journals, and specifications it is commonly implied that Portland cement is uniform; that cement from any source may be used just like cement from any other source; but experience in testing and using cement shows that, instead of being uniform, cement is a various material and that some cements are not well suited to certain special services,

for example, hydraulic structures. It is encouraging to know that a fundamental study of hydraulic cements has recently been undertaken at the U. S. Bureau of Standards with the co-operation of the Portland Cement Association, and that a number of engineers have been giving thought to this branch of the subject. In this connection reference should be made to the paper by William G. Atwood and A. A. Johnson, Members, Am. Soc. C. E., entitled "Disintegration of Cement in Sea Water".*

Engineering Foundation is aiding the Committee on Arch Dam Investigation, made up of members of the Society. Its experiments on the Stevenson Creek Test Dam, near Fresno, Calif., and on concrete used in that dam, and its observations on existing and proposed dams, should add knowledge that would be helpful to engineers designing and constructing dams of several types. This project has already been described.†

Luigi Luiggi,‡ Hon. M. Am. Soc. C. E.—This is a most valuable paper. Greater information is to be obtained from structures in a critical condition or from disasters than from those that are physically successful. Engineers, like physicians and surgeons, to become experts must operate on bad cases.

The paper emphasizes three important factors in a successful work, that is, design, materials, and supervision during construction. Dams, even in the most favorable circumstances, are difficult structures to build; and often the design has been considered more as a calculation of stresses than as a construction problem. Indeed, the design is an exceedingly important factor, for a badly designed dam is destined sooner or later to fail; but it is not sufficient merely to design the dam well—it is necessary to choose the materials best adapted to the conditions of the locality of the work. In particular, the cement must be of the highest class and be used in quantities substantially in excess of the theoretical proportions to allow for losses and deterioration.

It is easy to test cement in a laboratory and from the test to specify the exact proportion; but in the field, at a distance from the cement factory and lacking good material, it is necessary to adopt precautions that only practice can suggest. Consider the case of the Gem Lake Dam. The cement traveled over a normal railway, a narrow-gauge railway, then across a lake, and finally up a mountain side. It thus became very expensive; and when a material is costly there is always the temptation to use it sparingly. That is bad economy. Instead, more than the computed quantity should have been used to counterbalance the inevitable local losses: The wind blows some of it away, some of it sticks in the mixer and in the chutes. The best practice is to use 5 to 10% more than the theoretical quantity or even more than this under especially difficult conditions. It is bad economy to make weak concrete; this is dearly paid for later in the cost of repairs.

If the builders of the Gem Lake Dam had been more generous as to the cement, the concrete would have been less porous, and all the heavy expenditure to remedy this condition would have been avoided. As an adjunct to

* *Transactions*, Am. Soc. C. E., Vol. LXXXVII (1924), p. 204.

† *Proceedings*, Am. Soc. C. E., October, 1925, Society Affairs, p. 340.

‡ Hon. Pres., State Council of Public Works; Insp. Gen. of Civ. Engrs.; Prof. of Hydr. Eng., Univ. of Rome; Member, International Technical Committee for the Suez Canal; Senator, Rome, Italy.

good design, a proper proportioning, a particularly good cement, and an excess of it, are indispensable for hydraulic work that must not be porous.

A third necessary precaution is a thoughtful and conscientious supervision of the work. To impress these three points more deeply on the minds of engineers—especially younger engineers—the speaker will instance a multiple-arch dam which, in height, design, and general dimensions, was practically a reproduction of the Gem Lake structure. The failure of this dam in the Valley of Gleno, in Italy, high up in the Alps of Bergamo, caused an immense loss of lives and tremendous damage. This dam was built about 6 000 ft. above sea level in a very cold climate and with difficult transportation.

As to design the Gleno Dam, although not excellent, was fairly good; but the materials were rather bad and the supervision even worse. The work was begun during the World War. Cement was scarce and costly because all building materials were going to the front. Workmen were scarce—either older than 50 or younger than 18 years of age—and unskilled. Supervision was almost completely lacking. The work was mainly under the supervision of a manufacturer, a self-made man, exceptionally clever as a cotton weaver, but with little experience in construction work. Under him were only ordinary workmen in charge of the construction. The work was carried out trusting to Providence.

During that time and for a few years after the war, Italy had a very inefficient Government; Socialists, not to say Communists, easily imposed on the Government officials, who were powerless. This employer was permitted, therefore, to proceed, carrying out this dangerous work without any technically competent man to advise him. Although Government officials occasionally went to inspect the progress and reported that the work should be stopped, should be partly demolished and rebuilt, still nothing was done to effectuate this. Further, because coal was extremely expensive and difficult to obtain and because hydro-electric power was the only remedy for the lack of coal, water was allowed to impound behind the dam, to produce as soon as possible the electric energy which, in turn, would keep the cotton mill busy and provide cloth for soldiers and work for the men at home. When the war was over, little was done to remedy this state of affairs.

As the dam was leaking in many places, some inefficient repairs were made, but these did not cure the consumptive condition of the whole structure. Then came a rather heavy storm, almost a cloudburst; the spillway was not large enough to discharge all the surplus water, which rose behind and nearly overtopped the dam. It was only a question of minutes, as described by an eye witness, before the dam began to crack and suddenly burst. This happened during the night. In the valley below several hundred people were killed and damage estimated at 150 000 000 lire was done. Many of the people were drowned in their beds.

As a result of an inquest into the cause and responsibility for this terrible disaster, some men were imprisoned and now have to answer for the disgraceful condition; but no one can resuscitate the drowned, nor compensate for the property destroyed. It is more to the point to search out the reasons for failure and thus avoid the mistakes made in the Gleno structure.

Although its design was questionable, with excellent materials and good workmanship, conscientiously controlled, the structure might have stood; but the defectiveness of the cement, the porosity of the concrete, and the badly built masonry which allowed water to percolate, were the main causes of the failure. In addition, there was an underlying mistake in the foundation, namely, a large mass of masonry which blocked up the bottom of the gorge and formed a platform on which the dam rested.

So poor was the cement mortar in this block, that it allowed water to pour out through the masonry. Worse still, it was not founded by means of proper steps cut out of the rock, but was laid on top of the natural surface which had been rubbed smooth by glacial action. No cut-off trench was provided to prevent leakage and consequent uplift. The only precautions taken were to grout iron bars into the rock where it was too smooth and thus, one might almost say, to nail the dam to the foundation. As a result of all these dangerous factors, the percolating water must have exerted an uplift, and when this occurred the masonry must have moved slightly, the iron bars lost their grip, and the whole structure slid down to destruction over a part of the dam where these treacherous foundations existed. Thus, the disaster was due primarily to lack of proper and skilled supervision.

State authorities should always insist on the advice and inspection of competent engineers. The author states that "for such localities [the Gem Lake Dam], a dam of the rock-fill type has many advantages over dams of other types." The speaker fully concurs in these conclusions; it is certain that in the case of the Gleno Dam, if a rock-fill structure had been built—which during the war could have been effected more easily than the multiple-arch dam—the disaster would have been avoided.

Regarding the use of preparations like "Ironite", the speaker's experience of more than forty-six years convinces him that it is impossible to construct masonry and make it absolutely impermeable under a head of more than 40 or 50 ft. Not even a coating of neat cement, applied with a cement gun, will resist the percolation of water, because, besides stresses due to water pressure and change of temperature, there is another important effect, often disregarded, namely, the slight imperceptible movement of the crust of the earth to which the structure is subject almost daily. On a large scale these movements become earthquakes; but the very small daily tremors, noted only by seismography, cause the masonry to develop small hair cracks, which enlarge little by little and allow the water to percolate. In addition, the filling and lowering of the lake causes an elastic movement of the dam and of the foundation, which produces slight stresses that result in hair cracks. The great dam of the Murrumbidgee River in Australia is an illustration of this condition. The structure is about 240 ft. in height and the enormous pressure of the water causes actual movements in the foundation, as have been clearly recorded by seismographs set up in that locality.

Although it is possible to make masonry water-tight for some time by using special compounds, these infinitesimal movements, as years pass, will cause the masonry to crack. The speaker believes there is only one way of

making the surface impermeable—at least as nearly so as possible—and that is by covering the up-stream face with a membrane of sheets of bitumen, now commercially available in sizes about 4 ft. wide by 10 to 20 ft. long and $\frac{1}{8}$ in. in thickness. These should be made to overlap and should be fused together with hot tools to form a plastic, continuous, and absolutely impermeable coating over the masonry. To protect this sheet from summer heat, floating logs, and blocks of ice, a revetment of masonry 1 to 3 ft. in thickness must be provided.

The durability of bitumen is attested by archeologists who have found in Nineveh sewers made with brick laid in bitumen which is still impermeable after 3 000 years. The speaker's belief that the Gem Lake Dam could have been properly protected in this manner, is strengthened by the instance of a rock-fill dam in the Alps, the Devero Dam. The up-stream face of this dam has a sheet bitumen coating protected by masonry $1\frac{1}{2}$ ft. in thickness at the top, increasing to nearly 3 ft. at the bottom. After twenty-five years this dam shows no sign of leakage.

THADDEUS MERRIMAN,* M. AM. SOC. C. E.—The buttresses and the arches of the Gem Lake Dam were both made of the same concrete. In the buttresses this concrete endured, while in the arches it failed. The paper seems to demonstrate that concrete which is serviceable in one exposure is not necessarily serviceable in another.

Mr. Flinn has made a fair statement. Much good concrete has been placed, but there has also been some of doubtful quality. All concrete which disintegrates is not bad because the cement with which it was made was poor. Many of the troubles with concrete seem to be due to the fact that those who make it do not fully appreciate all the conditions which the process of concrete making involves. The speaker is free to admit, after many years of study, that this great problem still seems to be far from final solution.

On September 16, 1925, the speaker mixed a Portland cement with 43% by weight of water and poured a part of the mixture into one bottle and a second part into a second similar bottle. Forty-eight hours thereafter the first bottle was broken and the cement specimen so formed has since been exposed to the air. Twenty-one days later, on October 7, 1925, the second bottle was broken, and both specimens are here for examination. The first is soft and chalky, while the second is hard and dense. These specimens appear as if they had been made of entirely different materials, but, in fact, they are merely a demonstration of a difference in curing conditions. This is a simple experiment and one which all may profitably try.

The first of these specimens was treated in about the same way that most concrete is treated. It was put into a form, the form was pulled off at an early age, and Nature took its course. The specimen immediately dried out, leaving the hydrations uncompleted. In the second specimen, however, the conditions were such that the hydrations went on to practical completion and the resulting texture indicates a strong, hard, and durable material. Concrete so cured would be a wonderful compound.

* Chf. Engr., Board of Water Supply, City of New York, New York, N. Y.

Between the texture and the quality of these two specimens there are many intermediate kinds of texture and quality. Under one condition of curing, one quality of product is realized; under other conditions, other qualities result. Some are good, some are indifferent, and some may be decidedly bad. So it is that one structure is very good, while another in the course of a few years may show serious disintegration. The quality of a concrete is not only a function of the conditions under which it was cured, but it is also dependent on the conditions of subsequent exposure. A thoroughly cured concrete, all other conditions being the same, will resist almost any exposure. A partly cured concrete, depending on the conditions of exposure, may or may not prove to be satisfactory.

The curing of concrete, and particularly that in thin sections, is, in large measure, dependent on the weather and moisture conditions during the first five or six days following its placement. If the humidity be low, nearly all the water necessary for the completion of the reactions will be lost, while, if the air be moist or water supplied, the hydration of the cement will proceed in an orderly manner. It has been claimed, if the process of hydration be interrupted, and if water be supplied at a later time, that the hydrations will resume themselves. No proof of this supposition has been adduced. Such evidence as the speaker has been able to develop is to the contrary. If the first specimen described is given plenty of water at any time after it has been dried out, it will never take on a texture resembling the second.

In the case of the Gem Lake Dam, all the conditions for rapid drying out were favorable. The high altitude, and the consequent low humidity, did its fatal work in withdrawing from those thin sections the moisture which was the very life blood of the cement. For weeks, and possibly months, that cement product was athirst. It was like the first specimen previously mentioned—spongy, chalky, and unstable. It could not resist the solvent effect of the water, and its constituents were leached out. On the other hand, that same imperfect cement product, in the buttresses, served its intended purpose. Freezing was not the primary cause of this disintegration. Frost merely hastened the visible evidences of deterioration. The quality of a cement product is always dependent on the maintenance of an environment in which the cement reactions may complete themselves. Good concrete can be realized only if it is kept for several days after making, under such conditions as will insure for the cement an opportunity to develop its latent possibilities. These conditions are clearly indicated by the bottle experiment which has been outlined.

In many cases the treatment accorded to concrete after placing is analogous to that of abandoning a two-day infant to its fate. On State highways it has been learned that curing is one of the most important single operations in the entire process of concrete making. In many other situations, however, concrete after placing is allowed to shift for itself and then, as in a post-mortem investigation, the causes of disintegration are vainly sought.

The problem of durable concrete is the problem of durable cement. With a given cement the best results are not possible of attainment unless that

cement be used with understanding skill of workmanship. Cements differ among themselves and results which can be obtained with one cement are impossible with another. The task which confronts us is twofold: First, we must learn to differentiate cements with respect to the quality of the hydration products they are capable of producing; and, second, we must learn how to use a cement of given quality so as to secure the results which any particular situation demands.

At present, none of these matters is susceptible of standardization. Standards of measure are useful as means of convenience and of comparison. Standards of quality and of methods operate to suppress individual initiative. Standards imply averages, and if quality of product be a consideration they tend toward mediocrity.

In this great matter of concrete and of cement we cannot rest content with averages and with mediocrity. Until the uttermost of the problem is within the grasp of our understanding we must do no less than seek for the very best within the present possibility of attainment.

M. M. O'Shaughnessy,* M. Am. Soc. C. E. (by letter).—The authors are to be commended for their frank discussion on the repair of the buttressed arch dam in the high Sierras near the State of Nevada, south of Lake Tahoe, California. No estimate has been furnished as to the resultant losses sustained by The Nevada-California Power Company due to the two years failure of this dam to function in storing water, which losses must have amounted to far in excess of the cost of initially building a properly designed dam of a type suited to the conditions and available materials. It is hoped they will furnish these data before closing the discussion, so that a frank statement of all conditions may be available to engineers interested in this type of dam.

The building of this dam followed the conventional design for this type of structure at the date of its construction (1916), and the failure is not primarily due to theoretical design features. Its designer, after describing it in a paper† before the Society, deservedly received the Norman Medal. He was retained by the writer in 1917 to aid Assistant Engineers McIntosh, Nishkian, and the late Mr. Wood in designing the Lake Eleanor Dam, 70 ft. high, 1 200 ft. long, on the Hetch Hetchy Project. Further studies on the design for this type of dam resulted in several beneficial modifications being incorporated into the Lake Eleanor Dam,‡ which is a structural and economic success.

The true principle controlling dam design and construction was tersely elucidated by Mr. George L. Dillman,§ namely, that there must be only one impervious surface next the water, and that this face must be adequately supported by solid masonry, buttresses, rock, or earth-fill, depending on the locality and the type of dam.

* City Engr., San Francisco, Calif.

† "Multiple-Arch Dams on Rush Creek, California," by L. R. Jorgensen, M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. LXXXI (1917), p. 850.

‡ *Engineering News-Record*, September 4, 1919, p. 455.

§ *Transactions*, Am. Soc. C. E., Vol. LXXV (1912), p. 52.

The term "multiple arch" as applied to this type of dam is a misnomer; there are so-called "multiple-arch" dams in India 120 years old, and the name is meaningless as to design. This particular type of dam survives because of the buttresses, and the principles and reason for its selection were first described (after a structure built in Oregon) in 1902 by Mr. Dillman,* and due credit should be given him for his initiative in recommending it.

Overtopping the Gem Lake Dam with 4 in. of water is not a very severe test. The Upper Otay Dam (a single arch), in San Diego County, 84 ft. high, built by laymen without engineering skill, was topped to a depth of 30 in. without injury. However, an enlarged spillway now prevents a recurrence of this happening.

The sections are so thin in the buttressed arch type of dam that it is essential to have the concrete of such density that it will be water-proof, and this can be accomplished only by a careful selection and proportioning of the materials, avoiding an excess of water in mixing, and thoroughly spading the concrete after it has been deposited in the forms.

The writer's impression of the value of alleged water-proofing compounds on concrete surfaces subjected to water pressure is in entire agreement with the experience of the authors; that is, these compounds have no worth except to their manufacturers' and salesmen.

The concrete in the Gem Lake Dam failed because it was defective in that it was porous, thus allowing the water to penetrate it, and, with the heavy frosts and ice formation, permitting destructive disintegration to set in.

Why was the concrete porous? It may have been due to an excess of granite, mica, dust, and clay in the sand, or defective cement; or, as Mr. Jewett states:

"* * * the presence in the rock used as aggregate—which was obtained from material near the site of the work—[cheaply, of course, which feature should not be considered in dam construction] of thin, flat, smooth-surfaced pieces, which would have somewhat the same effect in concrete as mica in a sand mortar."

This class of rock prevents the proper interlocking of the remainder of the rock in the mass, and has a tendency to reduce the density of the concrete; and it is in such a situation that the experienced man, with judgment of materials, is needed fully as much as the designing engineer or the testing laboratory in determining the character and suitability of the materials to be used in the structure.

In building the 396 000-cu. yd. concrete dam at Hetch Hetchy, the engineers had quite a controversy with the contractors on their initial attempt to use a readily accessible, cheaply obtained sand. Exhaustive tests were made on samples of concrete and briquettes from this sand. They were found to be defective and failed to show the proper strength and hardness characteristics under time tests. The chemist's analysis subsequently disclosed the fact that the sands were heavily coated with a black compound which was largely tannic acid (from a dense grove of oak trees) and which caused the trouble.

* "A Proposed New Type of Masonry Dam," by George L. Dillman, *Transactions*, Am. Soc. C. E., Vol. XLIX (1902), p. 94.

Three miles up stream from the dam, at the junction of Tuolumne River and Rancheria Creek, there was found a bank (250 000 cu. yd.) of excellent sand which, after some protest on the contractor's part (because of the necessity of building a 3-mile narrow-gauge railroad to reach it), was used with very satisfactory results.

Evidently, Mr. Jewett's experience as a testing engineer indicates a doubt as to the value of the ordinary contract system for dam construction, since the tendency is to slight this class of work because of the contractor's desire for speed of operation and profit; this agrees in general with the writer's ideas. It may be mentioned in this connection that Lake Eleanor, Early Intake, Cherry Diversion, and Priest (145 ft. high) Dams were not built by contract, but in a very satisfactory manner under the direct charge of the resident engineers; and the O'Shaughnessy Dam at Hetch Hetchy was built by contractors who faithfully and promptly complied in every respect with the wishes of the resident construction engineer, who was assisted by a staff of twenty men, inspecting and testing.

In December, 1923, the Gleno Dam (buttressed arch type) failed in Italy, drowning 500 people and damaging property below to the extent of $5 000 000. No doubt, inadequate preparation of the foundations, together with defective lime masonry and concrete, put in without engineering control by the overzealous contractor in critical parts of the structure near the base, without Government supervision, caused the accident.

There is now a barrage of literary experts for contractors and damage claimants mailing reports back and forth on the causes of and responsibility for this failure, with one certain result, namely, that the Italian Government is allowing no more questionable dams to be erected by any one, and has commissioned skilled Government engineers to inspect all materials and supervise all designs, so that there will be no repetition of the Gleno Dam disaster.

It is a pleasure to note that an engineer of extensive construction experience, such as Mr. Huber, endorses the virtues of a rock-fill dam for this type of location, with its abundance of cheap rock, thereby saving the expensive hauling of cement.

The Morena rock-fill dam, built under the writer's direction, survived the cloudbursts of 1916 in San Diego County, California, when the Lower Otay Dam failed, and when every county and railroad bridge in that community was destroyed by floods.

The idea of the rock-fill type of dam is traveling eastward, crossing the Mississippi River, as witness the Dix River Dam, 280 ft. high, in a limestone formation, in Kentucky, built for the Middle West Utilities Company by L. F. Harza, M. Am. Soc. C. E., to conserve water for power.

Although time and the financial exigency in 1917-18 compelled the City of San Francisco to build the buttressed arch Eleanor Dam (forming an 8 000 000 000-gal. reservoir at a cost of less than $300 000), definite plans are now being made for practically scrapping this structure, and substituting the ultimate dam of the rock-fill type at this point. This rock-fill dam will be below the present dam, using the 70-ft. concrete buttressed arch for the lower

part of the up-stream toe or water-tight skin, and carefully placing and thoroughly grouting rock in layers, with spalls behind the arches to give them adequate support and so prevent their failure.

The writer would strongly urge all engineers first to heed the careful words of Mr. Dillman on design; next to examine exhaustively all the materials in the vicinity of any proposed dam that might enter into the structure, eliminating any cheap untried methods of experimenters and scrutinizing carefully vendors of special cheap types; then to select a type of structure that is best suited to the location and service required, regardless of the cost; and then to build so that it will not fail—not like Lord Macaulay's idea of the New Zealand tourist who, to illustrate the instability of things, was to stand on a broken arch of London Bridge and sketch the ruins of St. Paul's (London Bridge and St. Paul's are now being underpinned due to defective foundations in both structures, and the work is being done by British engineers).

J. B. Lippincott,* M. Am. Soc. C. E. (by letter).—The authors are to be commended for writing so frank a discussion of the failure of the Gem Lake Dam due to the freezing and thawing of the concrete on the outer side of the arches below the water levels in the reservoir. The use of this type of dam in regions subject to severe frost has long been a subject of conjecture among Western engineers. Although a thin shell of concrete may be made water-tight against percolation, it is not possible by any process known to the writer to prevent it from absorbing water when in contact with it. The Gem Lake Dam has shown that this is an unsatisfactory condition, in locations of extreme cold.

The multiple-arch dam because of the economy of its construction has such merit that its future use in many localities is assured. This type of structure, however, has its limitations which enthusiasts, in the past, have sometimes overlooked. Most of the dams of this type have had buttresses of plain concrete without reinforcement.

The writer has had occasion to examine the buttresses of five of these dams and in each has found one or more diagonal cracks in some of the buttresses, starting from the junction with the arch approximately two-thirds down from the top of the dam, and running in a line generally normal to the water face to an intersection of the foundation. These cracks do not extend into the reinforced arch rings. In one dam this type of crack developed prior to the time that the arch rings were built on the buttresses. In another instance the cracks are reported to have appeared after the arch rings were placed, but before the reservoir was filled. They are believed by the writer to be due to shrinkage caused by either the drying of the concrete or by temperature changes, because they open wider in winter and partly close in summer.

It is almost impossible to set up a triangular slab of concrete, say, 100 ft. high, with a base length of 100 ft. firmly anchored into bed-rock without having shrinkage cracks occur. This shrinkage and cracking of flat concrete pavements at intervals of 30 to 50 ft. is common. These cracks do not occur

* Cons. Hydr. Engr., Los Angeles, Calif.

in all the buttresses of the dams examined, but usually in a number of the higher ones. Some cracks of this kind have been noticed, however, in buttresses that are not more than 30 ft. high. In every multiple-arch dam having an age of, say, two years, that has been examined by the writer, such cracks have been found, including one having reinforcement.

It is believed that these cracks do not indicate a failure or any serious weakness of the structure, but they are disturbing and lead to discussion and comment. They distinctly suggest the necessity of thoroughly reinforcing the buttress walls of multiple-arch dams in order to minimize such conditions. This paper does not mention any such occurrence in the Gem Lake Dam, but as attention has been called by the authors to some of the limitations in this type of structure, it is deemed appropriate to call attention also to an improvement of past practice.

OREN REED,* JUN. AM. SOC. C. E. (by letter).—The writer has followed the fortune of the Gem Lake Dam with a great deal of interest. The Company with which he is associated has plans for two regulating dams on the North Fork of Kings River on the west side of the Sierras, at elevations of 6 550 ft. and 8 170 ft. The failure of the Gem Lake and other dams leaves a doubt in the minds of engineers as to the permanency of such structures when subject to the action of frost and ice. On the other hand, Lake Eleanor Dam,† 4 660 ft. above sea-level, of the multiple-arch type, has withstood frost action without damage, and several dams of the Ambursen type have been built in Canada and the northern part of the United States with slight damage from frost.‡ The Southern California Edison Company is constructing a multiple-arch dam at Florence Lake on the San Joaquin River, at an elevation of about 7 200 ft.

One wonders whether the primary cause of the failure of Gem Lake Dam was frost action or whether frost action was made possible by a weak porous concrete. It would have been of interest if the authors had stated whether the Agnew Lake Dam had also been damaged by frost, since it is only 550 ft. lower in elevation.

Since information as to the destruction of concrete by acidic and even pure water is very meager, some discussion on that important subject may be of value. While in Europe in 1922-23 the writer was much impressed by the general interest among engineers in this subject. Many tests of concrete, as used in the construction of dams, have been made in Germany, Denmark, and Norway during the last few years.§ It was found that some dams had been failures, but as a rule these failures had been of a purely local character and could be laid to poor workmanship and frost, and a few to poor sand, etc. In other cases the weakening had been more general, especially where water had an opportunity to work in porous concrete. There are several factors which were thought to have contributed to these failures.

‡ *Loc. cit.*, September 3, 1925.

§ Ing. Bonde, *Teknisk Ukeblad*, No. 14, April 3, 1925, and Ing. Groner, *Teknisk Ukeblad*, No. 10, April 17, 1925.

1.—Sand.—Sand containing dirt, humus or humic acids was found to make poor concrete. Concrete made with humus-holding sand has a comparatively low early strength and must be kept moist while hardening in order to gain its normal strength. These humus materials can be disposed of by heating, and, in part, by washing. The sand used should be clean, sharp, and well-graded. Whenever crushed artificial sand is available or can be produced cheaply enough it should be used.

2.—Cement.—In many cases it was found that the cement was at fault. In almost all concrete construction only pure Portland cement is used. This is composed of about 63% lime (CaO), about 20% silicic acid (SiO_2), about 6% of clay and smaller parts of iron oxide (Fe_2O_3), magnesia (MgO), sulphuric acid anhydrate (SO_3), etc. In hardening after hydration lime is freed, which, together with water, forms lime hydrate ($Ca(OH)_2$); this comprises about 15% by weight of the cement's mass. Lime hydrate is soluble in water and is washed out of the structure by leakage water, and, under the action of the carbonic acid in the air, becomes carbonate of lime. This is the white coat to be found on the structure. By the dissolution of lime hydrate the concrete becomes more porous and the voids are filled with leakage water. When freezing takes place, the sand grains are further loosened. This dissolution of lime takes place most easily when the mixture is lean and when humic acid is present in the water or in the sand. Dissolution of the lime may be prevented by adding to the concrete mixture a material which, reacting with the free lime, forms an unsoluble compound, as a silicate of lime. For this purpose the Germans use trass. This is a pale yellow or gray volcanic rock found in the valley of the Eifel in the Lower Rhine. It is a wholly neutral material, but with lime undergoes a chemical combination, forming an insoluble silicate of lime. Finely ground brick clay has also been used with good results.

A concrete may be made water-tight by using a rich cement mortar, but this is a costly method. The French alumina cement, which is especially rich in clay (Al_2O_3), containing 36%, is very durable against acids.

3.—Water.—Water for concrete must be clean and free from organic matter. From tests it has been proven that a plastic concrete gives better results than a dry mixture. A plastic mixture gives a less porous concrete.

4.—Workmanship.—The fourth factor in concrete placing is workmanship. This must be high grade to insure the proper mixing and placing. Poor workmen can produce poor results with the best materials.

The natural lakes and meadows on the west slope of the Sierra Nevada Mountains are, in effect, marshes. To a great extent they are of glacial origin. In many cases large tracts of meadow or marshy ground are covered by water when a dam is constructed. Many tests, especially in Germany, have been made on these marsh waters.

Most marshes contain more or less sulphur compounds, in the form of gypsum, sulphuric pyrite, or even free sulphuric acid. It is well known that sulphuric acid and sulphate-holding water attack concrete by combining with the lime to form gypsum, which is soluble. Destruction by these sulphuric acid combinations occurs not only to new but to old concrete.

Furthermore, great quantities of carbonic acid are found in marshes, which combines with the lime of concrete to form soluble salts. The free lime is

thus seen to be the main point of attack and, to prevent failure of the concrete, the lime must be fixed. Tests on marsh water have given varying results but concrete made with it has become weakened sooner or later in nearly all cases. As a general rule the acids which may be present in a reservoir will be in a very dilute state and will not be effective but, where there are large marshy tracts near the dam, and especially with low-water level in the reservoir, the acids will no doubt have a certain effect on the durability of the concrete.

It is not only the sulphate and acid-holding water which damages concrete. Under certain circumstances, pure water, on account of its high dissolving power, may act equally as effectively as weak acids. The water from the granite regions near the crest of the Sierras will often be nearly pure.

In general, concrete tests are concerned only with strength without regard to density, but in dams density is very important. A dense concrete made of the best materials prevents attack both from weak acids and from pure water. A porous concrete has many points of attack for mechanical and chemical action.

Many multiple-arch and flat-deck dams have been successful in Norway and Sweden. One of the most important of these is Holmevand Dam, A/S Saudefaldene, in South Norway. This is a flat-deck dam of the Ambursen type, and is 740 m. (2 400 ft.) above sea level. Fjergeng Dam, in Central Norway, north of Trondhjem, is also a flat-deck dam. As a protection against frost action, it was provided with a vertical insulating wall between the buttresses on the down-stream side. At the Porjus Dam, in Sweden, just above the Arctic Circle, there are concrete arch spillways 648 ft. in length. The remainder of the dam consists of earth embankments faced with stone. The up-stream side of the crest of the concrete dam is inclined, in order to force the ice to break up and be pushed over the crest. A stone-protected dirt fill, furthermore, has been placed in front of the dam to insure against leakage, as in dams of the Intze type. This spillway structure is a modified Ambursen dam and consists of concrete arches between concrete buttresses. The arches in front, against which the fill rests, have a curved exterior, while those forming the crest of the dam and the down-stream face are covered by a flat concrete deck paved with stone set in the mortar.

When it is guarded against, frost action of itself has no great effect on concrete in dams, but as a secondary factor it can do great damage.

B. F. Jakobsen,* M. Am. Soc. C. E. (by letter).—It would be hazardous in the extreme to conclude anything from the behavior of a single structure, and more especially since other similar structures subject to equally severe conditions, have shown no sign of deterioration.†

It would seem to the writer that some experiments on concrete made up of the material used in the dam and on other concrete, by subjecting it to

* Engr. in Chg. of Dams, Los Angeles County Flood Control Dist., San Fernando, Calif.

† See letter by M. M. O'Shaughnessy, M. Am. Soc. C. E., in *Engineering News-Record*, July 30, 1925, p. 194, stating that the Lake Eleanor multiple-arch dam located at an elevation of 4 660 ft. shows no sign of deterioration; also a letter by Spencer W. Stewart, M. Am. Soc. C. E., in *Engineering News-Record*, September 3, 1925, p. 396. Mr. Stewart states that a record of about seventy-five Ambursen dams built in Canada, in the Northwest, and in the New England States, shows that only three dams have deteriorated. Many of them are subject to minimum temperatures of between 40 and 50° below zero Fahr.; the oldest of these dams was built 22 years ago.

water pressure and freezing, could not have failed to throw some light on the subject; they might have furnished some explanation as to why this structure has deteriorated while other structures have not. The mere statement that a structure has deteriorated, while another has not, is of no great value to the engineer, who needs to know the why and wherefore—the *modus operandi*, so to speak—so that he can guard against a repetition.

The authors state that the gravity section is heavier than "standard profiles" of gravity dams. There are gravity dams in existence with base widths of from 64% to in excess of 90% of the height. What is meant by "standard profile"? A dam with a base width of 64% has no provision for uplift; but that can hardly be termed standard. In Italy and Switzerland, where there are Government provisions governing the construction and design of gravity dams, uplift must be included in the design and this was also true in France until recently. The new French regulations do not prescribe uplift, if the dam is provided with proper drainage, not only at the foundation, but throughout the structure, since a construction joint may be quite as weak as the joint at the foundation. The new French regulations, however, prescribe such moderate maximum stresses, that for a dam of any magnitude it is the same as if uplift were included. When a base width in excess of 81% is obtained it is quite immaterial whether this is accomplished by considering uplift or by lowering the maximum permissible stress.

The authors also state:

"It is not believed that stresses can be induced in the gravity section by pressures on the upper 30 ft. of the dam, because such pressures will be transmitted direct to the buttresses."

This may be an important question, however, and therefore well worth investigating, rather than leaving it to an offhand assumption. The multiple-arch dam is a much more elastic structure than a gravity dam and the writer's guess would be that the gravity dam might share to a considerable extent the load on the upper 30 ft. of the multiple-arch dam. Since a gravity dam—even the full section having a base width in excess of 81%—has a rather small factor of safety, an additional load applied at the crest and for which no allowance has been made might be a serious matter.

The writer wonders if any provisions were made to prevent the closing of the drain-pipes from the foundation by frost and what the factor of safety of the gravity dam would be in case these drains should become clogged by ice, or in any other manner, and the dam be subjected to uplift?

In the writer's opinion it is of no importance whether the maximum stress is 70 lb. per sq. in., as stated by the authors, or 170 lb. per sq. in., for this does not affect the safety factor in the least. The question is whether tension can be produced in the up-stream face when the dam is affected by adverse conditions.

J. D. Galloway,* M. Am. Soc. C. E. (by letter).—There seems to be no question but that the Gem Lake Dam was designed by Mr. Jorgensen in accordance with standard practice and that it was well built. The character

* Cons. Engr., San Francisco, Calif.

of the contractors would lead to the latter inference. All the usual tests of cement and sand were carried out.

The progressive failure of the structure is clearly presented by the authors. Over the entire length of the dam, in the zone covered by the winter fluctuations of the water surface, the concrete was disintegrated and the dam had to be rebuilt as described. The value of the paper lies in the description of the failure.

To make the proper interpretation of this or any other failure of an engineering structure is seemingly more difficult than to describe the failure. It is of interest to read the various explanations given by different engineers. Practically all point to the quality of the concrete as the reason for the failure, the idea being that it was the internal composition of that material that caused the failure and not some cause independent of the concrete. Mr. Jorgensen thinks the cement itself broke down during the coldest weather. The question immediately arises as to why the cement in the concrete above the highest water did not break down. This concrete was subjected to lower temperatures than that in contact with water on one side. The Agnew Lake Dam did not fail and there the water was not lowered during the winter.

The evidence seems to the writer to be most plain and the explanation given by the authors correct. The disintegration of the concrete was due to the freezing of the water which had entered into the concrete from the reservoir. The force developed when water freezes is enormous and will easily disrupt concrete. In fact, the same agency is responsible for the wearing down of dense rock masses such as native granite in regions subject to temperatures below freezing. In the present case the thin concrete of the arches permitted the water in the reservoir to be frozen into the form of a layer of ice on the water face, and in addition allowed to freeze whatever water may have been in the voids and hair cracks of the concrete. It is conceivable that cracks would develop in the concrete when on the water face the temperature was that of the water of the reservoir and on the air face the temperature was that of the air, admittedly far below freezing.

The breaking down of concrete by freezing in dams and other structures is not unknown—in fact, is fairly common. Evidences of this have come under the writer's notice and several instances are cited in this discussion. It is unnecessary to look for the fault in the concrete—the cause is found in the type of dam and the operation of the reservoir. It should be noted that in this region the low-water season may occur in the winter when all ordinary springs and streams are frozen. It is then necessary to draw on the reservoir. During a winter, the water surface will alternately rise and fall.

With the conclusions of Mr. Flinn the writer desires to differ in every respect. The danger in engineering is not to over-emphasize a failure of this type; the contrary is the case. Usually, the effort is directed toward minimizing, or covering up, or explaining away the failure. It is to the credit of The Nevada-California Power Company that it permitted the authors to set forth in detail the failure as it occurred. In most cases the endeavor of the company manager is to suppress all knowledge of such a failure. It is partly by failures of this type that the Engineering Profession

advances. The Gem Lake Dam was a test to destruction of a full-sized dam under operating conditions—a test of the most valuable kind. Tests to destruction are always the best, especially if the progress of the test is observed. No others can yield such valuable results in the form of knowledge. This is the type of test to be carried out on the Stevenson Experimental Dam near Fresno, Calif.

Again, little if any information would be gained by counting the dams that have failed and those that have stood. Engineering is not a matter of majorities, one way or the other. For example, there was a time in the United States and elsewhere, when the compression members of metal bridges were made of cast iron. Many of them held together, but some did not. It took the crowning disaster at Ashtabula, Ohio, to teach engineers that cast iron was an improper material for the vital members of a bridge. Notwithstanding the numerous bridges of that type then standing, engineers eliminated cast iron. Too much emphasis cannot be given the Gem Lake failure. It teaches that under such severe climatic and operating conditions, the multiple-arch dam with its relatively thin concrete, should not be used.

The writer also wishes to call attention to what is believed to be an unfortunate tendency among engineers and is exemplified in the present instance. As soon as a concrete structure fails, a number of commentators feel that it is necessary to rush to the defense of concrete as such, and endeavor to explain the failure by citing some unusual defect. In this case, some think that the small percentage of clay and silt explains the whole matter. Possibly so, but the evidence is all to the contrary. As a rule, a small percentage of silt renders the concrete more water-tight. Comparison is made between the structure that failed and some ideal concrete that is sometimes obtained in the laboratory and rarely if ever in the structure as built. Engineering structures are built of the materials at hand. There are regions in the West, of volcanic or granite formation, where it is impossible to obtain anything but a medium quality of sand or rock. Construction, even under the best of supervision, is always subject to conditions that make the resulting structure far short of the ideal. This imperfect structure is the one that engineers have to deal with and that sometimes fails—not the ideal one for which everything is perfect. Although always striving for the very best, the Engineering Profession should design in the light of information obtained in actual practice as to just what degree of perfection may be realized in the structures built under ordinary conditions.

Mr. Jorgensen undoubtedly feels chagrined over the failure of the dam. The writer believes this to be largely unnecessary. His dam was well designed in accordance with good practice, and it was reasonably well built. It resisted the stresses of the water, but failed gradually under severe climatic conditions coupled with certain operating conditions not usual in many cases.

The value of the failure at Gem Lake will lie largely with those who interpret it correctly. To those who see in it merely another example of a defective type of concrete, to be added to the thousands of such examples already existing, the failure will be of no value. To those engineers who

find in the combination of thin concrete arches, severe climate, and rather unusual operating conditions an explanation of the failure, the lesson will be of the utmost value. Had Mr. Jorgensen had before him a similar example when designing the Gem Lake Dam it is conceivable that he would have adopted another type. Therein lies the value of the lesson of this failure.

I. OESTERBLOM,* M. AM. SOC. C. E. (by letter).—This paper is unusually interesting and raises again a question that is causing anxiety all over the world. Slow disintegration of concrete, substantially as described at the Gem Lake Dam, seems to cause even more trouble and anxiety in the tropics. Naturally, one is, therefore, led to ask: Is it really the cold that does the damage? This is usually assumed—it seems so obvious; but the obvious is not always correct and is very often far from correct.

In the case under discussion it may be the cause in part, but there also seems to be evidence of other causes. Under the heading, "History of Operation" (page 715), it is stated that: "During the eight years of operation of the structure, very few cracks occurred in it." This does not seem to be the behavior of cold weather which acts on entrapped water with a great deal of violence and speed. The force is evidently of a slower nature, but is none the less very destructive.

There is further evidence that it was not frost that caused the essential part of the destruction. Referring to the first paragraph under the heading, "Condition of Dam in 1924" (page 723), it is stated that in the intervening middle belt, the concrete had become dead and inert, but that a section at the bottom of each arch was little affected. If frost had been the cause, would not the effect have been general?

The subsequently recorded opinion of investigating engineers would seem to be inconsistent. If there was sufficient porosity to permit percolation, the destruction, by necessity, would have taken place during the first winter after construction, but this Mr. Jorgensen, himself, is able to disprove by very competent evidence—his own records—long before any trouble was anticipated. The paper also states that "during this time [two years] no change in the structure was apparent." The concrete evidently was most excellent and of the highest consistency.

Everything seems to point to a more insidious force than mere frost and water. The writer suggests the supplementary compressive forces due to the colloidal expansion of the silica gels that make up the cement.

It would be interesting to know where the cracks really occurred from the viewpoint of stress calculation based on such expansion, in addition to the usual effects of gravity and temperature. Such calculations, compared with the actual records of the cracks, would really be conclusive.

Colloidal expansion is also due to presence of water but in very small quantities only and in such a state, ordinarily, that frost would have no direct effect. Even in the best of concrete this water is present and it is only necessary that the external water should vary—as it did in this case—in order to set up a change in colloidal absorption and subsequent variation of internal

* Care, Truscon Steel Co., Youngstown, Ohio.

stress. It is well known how destructive such variation of stress is; it is also known how slowly it works and that a catastrophe, due to such conditions, sometimes may come without warning and most unexpectedly if special precautions are not taken.

It would seem that the destruction recorded at the Gem Lake Dam is an ideal example of how a most excellent piece of construction is being slowly destroyed by colloidal action. At the same time it offers another opportunity for the engineer to take a decided step forward in technical progress.

Destruction similar to that recorded is general in the tropics even to such extent that in certain parts competent engineers refuse to use concrete for permanent construction. The basis there for the change in colloidal absorption and subsequent stress variation is the monsoonal change, with some months very dry and others very wet. A comparison between conditions and effects in cold and warm climates is interesting, and the matter has been discussed.*

B. C. Collier,† M. Am. Soc. C. E. (by letter).—The writer has read with great interest the various points brought out in the paper, the discussion regarding the failure of the concrete in Gem Lake Dam to withstand the effects of cold or other disintegrating agents, and especially the statement in the Synopsis (page 713) relative to the necessity of providing a "positive and permanent method of water-proofing concrete."

For several years he has been an earnest advocate of the necessity of proper selection of aggregates in order to insure the life of concrete structures, especially when subjected to water conditions. The statements made by several discussors, to the effect that a very probable cause of the failure was the use of limestone as the aggregate, are fully in accord with his experience. For a number of years he has believed that concrete will not withstand the continued action of water pressures especially when it is in thin slab sections. Examination of a number of reservoir and similar linings seems to prove that the continued passing of minute quantities of water through the pores of the concrete has the effect of a gradual attrition of the cement particles, and the consequent breaking down of the structure.

This discussion has also been of especial interest to the writer, because he was asked, during the period of construction of this dam, to pass opinion on the thickness of the gunite covering to be applied to the up-stream face as a water-proofing medium. At that time knowledge regarding such details was very limited, but the suggestion offered to the effect that at least 1 in. of reinforced gunite should be used, was not accepted as advisable. According to the paper a very thin coat ($\frac{3}{4}$ in. at the bottom and $\frac{1}{4}$ in. at the top) was applied without any reinforcement.

It is, therefore, of particular interest to note what the probable result might have been had a thicker coating of gunite with proper reinforcement been applied. All statements made are to the effect that for a period of almost three years no seepage through the dam was noted, but that subsequently this seepage occurred and gradually increased in volume. In a structure such as this the

* *Proceedings*, Institution of Engrs. (India), Yearly Meeting, Delhi, 1925.

† Pres. Cement Gun Company, Inc., Allentown, Pa.

alternate rise and fall of the water naturally causes severe stresses and a tendency to movement in the up-stream surface. Without question, this stress, continued over a period of time, caused the development of checks or cracks in the thin shell of unreinforced gunite, thereby ultimately defeating its original purpose, and allowing the passage of the water through the dense surface covering to the porous concrete beneath. Although, as stated, at the time at which this work was done little knowledge was extant regarding methods of water-proofing with gunite, later experiences have indicated that had a heavier coat of properly reinforced gunite been used, it would probably have prevented the seepage of the water and the consequent disintegration of the concrete whether due to faulty sand, faulty aggregate, porosity, or frost action.

It is interesting to note the suggestion made by some of the discussors that a coating of asphalt on the up-stream face would have resulted in the saving of the structure. In view of the statements recently made to the writer by several engineers in charge of large water-works activities, to the effect that not only is asphalt, when subjected to such conditions, not water-proof, but also that the life of a membrane coating under water does not exceed 15 or 20 years, doubt naturally arises as to the efficacy of such treatment. An engineer of wide experience in testing work has recently stated that he had definitely proven that asphalt would absorb moisture.

The writer has long been an ardent believer in the adequacy of Portland cement, when it is properly applied, as a resistant to water action. In order to produce this resistance it is necessary to provide a density of application similar to that of gunite. In addition, however, a broad experience in inspection of such structures as this had indicated the necessity of properly reinforcing the gunite slab in order to eliminate the breaking down by "weave" and constant movement; or to insure against the development of checking or cracking from internal stresses. Such authorities as F. E. Turneaure, M. Am. Soc. C. E., have clearly shown that cement structures should always be reinforced against the initial "setting up" stresses, and, in accordance therewith, the writer is now recommending that, for gunite slabs for water-proofing, reinforcement of not less than 0.3 of 1% should always be used, and that preferably, under such severe conditions as those at Gem Lake, the percentage should be as high as 0.5. This percentage of reinforcement placed equally in both directions will also provide an almost positive protection against cracks that will arise from expansion and contraction. With such reinforcement, and with a thickness of approximately 2 in. of gunite, experience has shown that the positively water-proof conditions specified by the authors as being necessary will be obtained.

Fred A. Noetzli,* Assoc. M. Am. Soc. C. E. (by letter).—It is well known that certain concretes are subject to deterioration from frost and other actions when they contain a considerable amount of moisture. The deterioration of concrete in sea water is a striking example of this phenomenon. In this case the physical effect of the expansion of the salt crystals which, under certain

* Cons. Hydr. Engr., Los Angeles, Calif.

conditions, may form in the pores of porous concrete in sea water is increased by chemical action. In hydraulic structures subjected to frost conditions the particles of water contained in the concrete will expand considerably when this water is transformed into ice, and thus tend to spall the concrete or weaken it otherwise. In passing from the liquid to the solid state, water expands with a force equal to about 150 tons per sq. ft. One cubic inch of water at 32° Fahr. occupies 1.09 cu. in. in the form of ice at 32° Fahr., which is equivalent in expansion to about one-tenth of the original volume. Porous concrete is, therefore, apt to suffer considerably from frost action. Dense concrete is known to be practically immune against it.

The authors point out that serious deterioration has taken place in the arches of the Gem Lake Dam where the concrete was subjected to water pressure at the time of low temperatures. On the other hand, M. M. O'Shaughnessy, M. Am. Soc. C. E., has stated* that in the Lake Eleanor multiple-arch dam, built in 1918, at an elevation of 4 660 ft., "there are no indications of wear and tear on this concrete structure, and the location is subject to severe frosts without any noticeable depreciation whatever in the concrete"; further, that, in his opinion, "the failure of the Gem Lake Dam is due not to design of structure, but to defective granite dust and materials being incorporated in the sloppy overwatered concrete during construction."

The writer can testify from personal knowledge that, also, the Bear Valley multiple-arch dam, located at an elevation of 6 700 ft., shows very little, if any, deterioration from frost action.

The Gem Lake Dam was built in 1915 and 1916. The Bear Valley and Lake Eleanor multiple-arch dams were constructed in 1912 and 1918, respectively. The Gem Lake Dam suffered from frost action, the other two dams are apparently as strong as at any time in their history, although the climatic conditions are similar at all three sites.

What was wrong, then, with the concrete of the Gem Lake Dam? The authors state that the upper 30 ft. of the existing arches and the buttresses supporting them appeared to be in perfect condition. Only that part of the arches which was below the reservoir level during the severe winter conditions was damaged. The temperature variations in the upper arches and the buttresses were at least as great as for the lower arches, and probably greater. It was, therefore, apparently not the low temperature itself that damaged the lower arches, but evidently the water which had been filtered into the concrete and which expanded when it was transformed into ice in freezing weather. Similar deterioration of concrete has been observed in many structures exposed to water and frost, in canal head-works as well as in some gravity dams many feet in thickness. In most of these cases, deterioration could easily be traced to porous concrete, or unsuitable aggregate, or both.

For the construction of the Gem Lake Dam, a lake sand, containing 3½% of clay and 1% of dirt, was mixed with the sand from the rock crusher in the proportion of about 75% of lake sand to 25% of crushed rock sand. It is not stated whether or not this sand was properly graded. The fact that compression tests on specimens made during construction showed an average

* In a letter to the Editor of *Engineering News-Record*, July 30, 1925.

crushing strength of the 1:2:4 concrete of only 900 lb. per sq. in. at the age of 14 days would indicate that the quality of the sand used was not at all what it should have been for this type of structure. Chemical decomposition of certain ingredients of the granite dust of the "crusher run" may also have been one of the reasons for the troubles with the dam.

The authors deserve credit for emphasizing the necessity of seriously considering frost action when designing dams for cold climates. The method of repair adopted for the Gem Lake Dam is about as radical and expensive as could be devised, but it may have been necessary in view of the advanced state of deterioration.

The writer believes that a satisfactory water-proofing of the arches, as originally attempted by the owners of the dam, could have been obtained in the following manner: At the time when the concrete of the arches showed signs of deterioration, the weak spots, leaky construction joints, etc., should have been cut out as far as practicable and re-filled, for instance, by means of a cement gun. Then a four-ply water-proof membrane of a Malthoid or Tartex product might have been applied in successive layers on the up-stream face of the arches, and a protection slab of concrete, from 12 to 18 in. in thickness, cast against the membrane. The four-ply water-proof membrane would have protected the old arches from infiltrations of water and thus have stopped further deterioration. The concrete protection slab, besides preventing injury to the membrane, would have added materially to the safety of the dam. A dense concrete such as was used successfully for the Lake Eleanor multiple-arch dam, referred to previously, would have insured the permanency of the protection slab. The cost of this concrete slab would have been relatively small as no forms would have been required for the under side of the slab. The water-tight membrane of the character described would have cost about 15 cents per sq. ft. in place. The quantity of concrete for a 12-in. protection slab from the bed-rock up to an elevation of 30 ft. below the crest of the dam, would have been approximately 1 250 cu. yd. This compares with the 12 000 cu. yd. used for the method of repair adopted by the owners of the dam. The multiple-arch type of dam has the advantage of offering easy accessibility to all parts of the structure. Repairs may be made, therefore, before the danger point has been reached.

In what follows, the writer wishes to make a few suggestions which may be helpful for avoiding in future thin dams some of the difficulties that have arisen in connection with the Gem Lake Dam.

The writer agrees with the authors that an impervious concrete will prevent the deterioration of concrete subjected to water pressure and extreme low temperatures. A careful selection and the proper grading of sand and gravel or crushed rock will go a long way toward accomplishing this end. A somewhat richer mixture than the standard 1 : 2 : 4 proportion, say, about 1 : 1.8 : 3.5, will furnish a dense and strong concrete at a comparatively small increase in cost per cubic yard. Naturally, proper care in mixing and placing the concrete is also of great importance.

The arches of multiple-arch dams should be designed so that for shrinkage, rib-shortening, and maximum variations of temperature the tension stresses

in the arches are safely within the tensile strength of the concrete. A liberal quantity of reinforcing steel should be added for additional safety. Special attention should be given to the preparation of construction joints between successive horizontal layers of concrete. Leakage is most likely to occur in joints that have not been properly cleaned of laitance and foreign matter. Attack by frost would inevitably start sooner or later in such joints, and the deterioration of the concrete would continue progressively. A 4-in. strip of galvanized iron, placed from 3 to 4 in. from the up-stream side of the arches, across all horizontal as well as vertical construction joints, will prevent leakage through the joints.

In important structures the entire up-stream face of the arches should be covered with a layer of properly reinforced gunite from 1 in. to 2 in. thick. Thin layers of unreinforced gunite, such as was used on the Gem Lake Dam, are not effective very long.

In spite of the partial disintegration of the Gem Lake Dam, the writer firmly believes that safe and permanent structures of the thin arch and multiple-arch type may be built in locations subject to severe weather conditions. A proper design of the arches, suitable, well-graded concrete materials, and careful mixing and placing of the concrete will result in structures which will be safe, water-tight, and permanent. A considerable number of such dams were built years ago and are satisfactory in every way. A few others, like the Gem Lake Dam, have given trouble for reasons which are fairly well understood by this time and can easily be avoided in future constructions.

A multiple-arch dam that will be 160 ft. high and more than ½ mile long is now (December, 1925) under construction in the high Sierras at an elevation of 7 200 ft. The multiple-arch type was selected for this structure after careful investigation of the probable causes that may have been responsible for the troubles on Gem Lake Dam.

The authors seem to favor dams of the rock-fill type for locations where extremely low temperatures may occur. Such rock-fill dams naturally would have to depend for water-tightness on a concrete core wall or on a concrete face slab. A loose rock-fill is relatively porous and permits of more or less free air circulation, including "chimney effect", that is, allowing the warmer and lighter air in the interior of the mass to rise and escape at the top of the dam, thus drawing in the cold outside air through the lower porous parts of the fill. The thin slab of a concrete core or face wall of such a rock-fill dam, therefore, would undoubtedly be subjected to some frost action, especially near the water line, which, in case of porous or otherwise unsuitable concrete, sooner or later would unquestionably lead to progressive deterioration of the concrete. Inasmuch as there would be no simple way of observing such deterioration of the most vital part of a rock-fill dam, a "blow-out" of a weak spot and a possible failure of the structure might occur in time.

According to the authors the Gem Lake Dam was overtopped during a severe flood to a depth of about 3 in. along the entire crest of the dam. Such conditions might have been disastrous for a rock-fill dam.

If on Gem Lake a rock-fill dam had been constructed, and if for the core or face wall the same kind of aggregate had been used with the same class of

workmanship as for the multiple-arch dam, it is possible that the authors would have had occasion to describe the failure of a rock-fill dam instead of giving an interesting account of the successful repairs of a multiple-arch dam.

F. W. Scheidenhelm,* M. Am. Soc. C. E.—The discussion by Senator Luiggi is of exceeding interest to the speaker.

Senator Luiggi is of the land which presumably was the first to develop cement, namely, the Roman or puzzolan cements. From much that has been said and written (not by Senator Luiggi) one would infer that Roman cements, or more particularly the structures in which they were used, are everlasting. If so, an important art has been lost. However, the speaker suspects that the long life actually enjoyed by certain Roman puzzolan cement-bound structures is due to the fact that, except for the northern part, Italy is not subject to a rigorous climate. Freezing either does not occur or is of minor extent. In fact, the speaker's personal observation on the occasions of two visits to Italy lead him to believe that, under similar climatic conditions, Roman cement-bound structures behaved much like Portland cement-bound structures of the present age. In neither case does the cement seem to be perfect. Even Italy, as well as America, has its problems as to the durability of hydraulic structures.

A Fundamental Question

The Gem Lake Dam is a hollow concrete structure which, by reason of disintegration of its deck, has failed to perform its intended function. Long before the presentation of this interesting paper there was raised in the speaker's mind the fundamental question: Is a hollow dam of concrete an appropriate engineering structure, particularly for cold climates? This question carries with it the premise that the concrete is of a kind which is practicable of attainment under the present state of the art. The question applies to hollow concrete dams of both the multiple-arch and the reinforced concrete slab-deck types. Study of this question has led the speaker into a fairly broad investigation and the occasion seems opportune for briefly stating the results and presenting his deductions.

At the outset it may be stated broadly that the investigation has left the speaker optimistic as to the propriety of the use of concrete in hydraulic structures which are exposed to severe freezing and thawing and, until there is further and contrary evidence available, his answer to the foregoing question is definitely, even though qualifiedly, in the affirmative.

Gem Lake Dam Disintegration

First consider briefly the conditions obtaining in the case of the Gem Lake Dam. The design involves relatively thin arches. The thickness was apparently from about 16 to about 34 in. within the areas of the arched decks where disintegration occurred. However, relatively thin decks, whether in the form of arches or reinforced concrete flat slabs, constitute an essential feature of hollow concrete dams. If the decks were not relatively thin, then

* Cons. Engr. (Mead & Scheidenhelm), New York, N. Y.

hollow concrete dams would lose a considerable proportion of any economy which they may offer. It is fair to state that the design of the Gem Lake Dam follows the general lines accepted as structurally satisfactory for dams of its type.

As to the concrete of which the dam was originally built, the facts available from published information and private inquiry are none too detailed nor reassuring. Among other things it is not unlikely that the sand was considerably too fine. The coarse aggregate is questioned by certain interested engineers, but the information available is not such as to cause the speaker to attach any serious blame to it. The cement was presumably of a quality equal to the average of standard Portland cements and subject only to the qualifications that there is still much to be learned about cement in general and that undoubtedly there are some steps still to be taken for the improvement of the product.

The proportions in which the arch concrete is reported to have been mixed, namely, 1 part of cement to 6 of aggregate, might be adequate if the other factors of the manufacture of the concrete in point were satisfactory. However, it seems not unlikely that the fineness of the sand would have warranted a somewhat greater cement content. Moreover, a greater cement content would have been desirable, if indeed not imperative, in case the water-cement ratio was relatively high. As to the latter, the speaker does not doubt that in conformity with general practice at the time of the construction of the Gem Lake Dam (1916) the water content was too great. (If the builders of the Gem Lake Dam erred in this respect, let it be noted that many others, including the speaker, have made the same error.)

The speaker has been unable to learn that any particular attention was paid to the adequate curing of the concrete and agrees thoroughly with Mr. Merriman that conditions were most unfavorable for proper curing. Although impermeability and permanence of concrete are not direct functions of strength, nevertheless, it is pertinent to note that the 14-day strength of specimens of concrete tested during the original construction was only about 900 lb. per sq. in. in compression. That fact in itself was none too good an omen.

The outstanding characteristic of the disintegration of the concrete is that apparently the arch mortar has tended to change from the original texture and strength to a texture and strength approximating those of hard clay, or perhaps even chalk. The disintegration is reported to have been limited to the deck arches, the buttresses remaining in good condition. Although presumably there was a tendency to require greater workability and, hence, a wetter mix for the arch concrete than for the buttresses, yet this possibility and the disintegration of the arch do not necessarily indicate that the arch concrete was inferior to the buttress concrete—in fact, the buttress concrete is reported to have had a somewhat lower cement content. It seems clear only that the arch concrete was not of sufficiently good quality to withstand the severe physical conditions to which it was subjected. It is likely that if the buttress concrete were subjected to similar physical conditions for an equal length of time similar disintegration would result.

As pertinent to the causes of the disintegration and the possible means for preventing similar disintegration in other structures, it is to be noted that apparently the disintegration occurred only below the winter water surface of the reservoir. The reservoir is reported to have been drawn down regularly for the winter period to a level about 30 ft. lower than the "pool-full" level. Correspondingly, the upper limit of the disintegration is said to have been about 30 ft. below the top. It is, therefore, a reasonable deduction that percolating water from the reservoir was a prerequisite of the disintegration.

On the other hand, the authors report that "a section of the bottom of each arch was little affected." Clearly the absence of disintegration in the lower part of the arched decks cannot be attributed to the absence of percolating water. It is true that the lower part of each arched deck is thicker than that directly above, but such a difference in thickness is too gradual and too minor in amount to afford the explanation. Instead the speaker is strongly inclined to agree with the authors in attributing that better condition to the protection afforded by the drifts of snow which lodge against the lower parts of the decks.* Precipitation appears to be plentiful and must be in the form of snow even before the temperature becomes very low.

The absence of disintegration in the lower parts of the decks indicates that percolation of reservoir water through the concrete is not necessarily, or at least not rapidly, harmful provided there is no severe freezing at the under side of the deck. (Whether in the case of even the best quality of concrete permitting percolation of water such percolation might not *per se* cause some disintegration in the course of a number of years is another question.)

The speaker inclines to the view that the disintegration of the arched decks at Gem Lake was due to the combination of inferior concrete, percolating water, and severe freezing alternating with thawing, and that, in the absence of any one of these three unfavorable factors, disintegration would probably not have occurred. In fact, the number of unfavorable factors may practically be reduced to two, for if the concrete were impermeable percolation could not have occurred. It is of special significance that the down-stream faces of those parts of the arched decks which suffered damage were at no time of the year protected by structural or natural (snow) enclosure against severe freezing.

Successful Unenclosed Hollow Concrete Dams

Engineers may well take cognizance of the fact that there are in existence a number of hollow concrete dams, both of the multiple-arch and the reinforced concrete slab-deck types, which, despite their locations in regions of rigorous climate involving alternate freezing and thawing, have continued to perform their intended functions and which have suffered no disintegration or, if there has been any disintegration, such disintegration has been too insignificant to record. This fact indicates strongly that such difficulties as have been encountered with hollow concrete dams have not been due primarily

* Charles W. Comstock, M. Am. Soc. C. E., has informed the speaker that he was told by members of the local operating staff of the Power Company that the near-by 30-ft. Agnew Lake Dam becomes completely covered with snow on its down-stream side.

to the thin decks, whether in the form of arches or of reinforced concrete plates. Also, it shows that concrete can be produced which, in the accepted sense, is permanent and can successfully withstand the rigors of such climates.

Agnew Lake Dam, California.—Of existing hollow concrete dams which are performing their intended functions the two which have the most direct bearing on the Gem Lake case are the Agnew Lake Dam (the mate of the Gem Lake Dam) and the Lake Eleanor Dam. The Agnew Lake Dam was built by the same company, by the same construction organization, and at the same time as the Gem Lake structure, so that it, too, has had a life of more than nine years.* It is situated on the same stream, at an elevation only about 500 ft. lower; hence, both dams are subject to practically the same climatic conditions. The Agnew Lake Dam, however, is only 30 ft. high and is in a small gorge, so that its crest length is only 280 ft. In consequence, the dam is reported to be snowed in every winter, with the snow on the down-stream side extending to the very top of the structure. Mr. Jorgensen, the designer of both dams, states that Agnew Reservoir remains practically full throughout the winter.

The design of the Agnew Lake Dam is the same as that of the Gem Lake Dam. In view of the low height of the Agnew Lake Dam, therefore, the thicknesses of arch decks subject to hydrostatic pressure from the reservoir during the winter are nowhere so great as in the cases of those decks of the Gem Lake Dam which have suffered disintegration.

The concrete of the Agnew Lake structure is practically the same as that at Gem Lake. The coarse aggregate was taken from Gem Lake to Agnew Lake. The sand apparently involved the only difference from the Gem Lake construction, as about one-half of it came from Gem Lake and the remainder from Agnew Lake itself. Hence in spots, at least, even the sand must have been the same as at Gem Lake; on the other hand, Mr. Jorgensen was of the impression that the local Agnew Lake sand was of the poorer quality. As regards water and cement contents and the method of making the concrete, the reasonable assumption is that there was no difference between the two structures.

Nevertheless, competent engineer observers agree that the Agnew Lake Dam is in first-class condition, having suffered no disintegration. Why, then, the difference? Presumably the unfavorable conditions as regards quality of concrete, percolation of water, and severity of climate are essentially the same. The one marked difference appears to be that involved in the complete snow covering, thus obviating severe freezing. The speaker agrees with Mr. Jorgensen in attributing the good condition of the Agnew Lake Dam to its snow cover protecting the down-stream faces of the arched decks.

Lake Eleanor Dam, California.—The Lake Eleanor Dam, of the City of San Francisco, located on a tributary of the Tuolumne River, is likewise of the multiple-arch type and is of approximately the same height, namely, 70 ft. gross against the 80 ft. gross height of the Gem Lake Dam. Lake Eleanor

* "Multiple-Arch Dams on Rush Creek, California," L. R. Jorgensen, M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. LXXXI (1917), p. 850.

Dam is on the western slope of the Sierra Nevadas at an altitude of only about 4 650 ft. above sea level, whereas the Gem Lake and Agnew Lake Dams are on the eastern slope of the same mountains at elevations about 4 000 ft. higher. Nevertheless, the Lake Eleanor Dam, too, is subject to the most important and severe element of climatological conditions—alternate freezing and thawing; in fact, the conditions at the Lake Eleanor site are, not unlikely, more severe in that, by reason of the lower altitude, the cycle of freezing and thawing may occur more frequently within a given time.

The panels of Lake Eleanor Dam between centers of buttresses are 40 ft., just as in the case of Gem Lake. Its length is approximately 1 260 ft. It was built in 1917-18 and the same engineer had an important part in the design of each of the two structures. Although there are certain differences in the thickness of members, these are relatively minor; it is fair to state that structurally the two dams are essentially alike. Furthermore, the likeness extends to the conditions of operation, for in each case the water surface of the reservoir is reported to be comparatively low in winter. Possibly there is somewhat more fluctuation of water surface during the winter season in the Lake Eleanor Reservoir than in the Gem Lake structure. As in the case of the latter, the Lake Eleanor Dam has no spillway apron, nor any other type of enclosure of the space between buttresses. Its spillway is in a solid gravity part of the dam.

That there has been no disintegration has been stated* by Mr. O'Shaughnessy, according to whose report, the present multiple-arch dam at the Lake Eleanor site is in due course to be displaced by a rock-fill dam. The ultimate dam is to be between 150 and 175 ft. high.† Apparently, the designers consider a multiple-arch dam—or a buttressed arch dam, in the terminology which they properly prefer—as being either unsafe or uneconomical for so great a height as that ultimately intended for the Lake Eleanor site. Nevertheless, the arched decks of the existing dam are intended to be utilized and relied on to furnish the lower 70 ft. of water-tight up-stream diaphragm for the ultimate, high, rock-fill dam. Evidently, those in responsible charge entertain no doubts as to the durability of this particular multiple-arch dam. Mr. O'Shaughnessy characterizes the Lake Eleanor Dam as being a structural, as well as an economic, success.

Aziscohos Dam, Maine.—A successful unenclosed hollow concrete dam which has had a fairly long life is the Aziscohos Dam, built in 1910-11, on one of the tributaries of the Androscoggin River in Maine. It is about 75 ft. high and the hollow concrete part is about 500 ft. long, of which one-half is spillway. The spillway portion has an apron extending down about two-thirds the way from the spillway crest to the foundation rock, but not a sufficient distance to have a material effect on temperature conditions in that part of the dam as compared with the bulkhead part, where there is not even a partial enclosure on the down-stream side.

The deck is reinforced and has a flat surface on the up-stream side, but is arched only on the down-stream side. The minimum thickness of the deck

* *Engineering News-Record*, July 30, 1925, p. 194.
† *Loc. cit.*, September 4, 1919, p. 466.

slab at the crown of the arches is apparently about 30 in. and the maximum about 36 in. The deck concrete is said to be of 1 : 2.5 : 3 proportions. A detailed description of the dam has been published.*

On the occasion of an inspection of the Aziscohos Dam in June, 1922, the only disintegration observed by the speaker was in the cases of two reinforced concrete brace-beams in the outlet bay, exposed to water and freezing. This good condition is confirmed by the observation of George C. Danforth, M. Am. Soc. C. E., who visited the structure in 1923. Admittedly twelve years is not a long life for a dam; on the other hand, in practically every case of serious disintegration of concrete the trouble has made itself known within ten years.

Eugenia Falls Development Dam, Ontario, Canada.—A hollow concrete dam exposed to temperature conditions approximating those of Gem Lake Dam is that of the Eugenia Falls development of the Hydro-Electric Power Commission of Ontario. This dam is of the Ambursen type, with the conventional reinforced concrete flat deck slab. It is situated about 70 miles northwest of Toronto, Ont., Canada, in latitude 44° 20′ North, where it is subject to a maximum annual variation of temperature of about 125° Fahr., ranging from 35° below zero to 90° above. The structure was completed in 1914, and thus has been in service for more than 11 years. It is about 50 ft. high and the hollow concrete part is about 1 250 ft. in length.

This part of the structure is entirely of bulkhead section, that is, open on the down-stream side, except a relatively short spillway the apron of which extends so short a distance below the spillway crest as to have negligible enclosing effect. During the winter the reservoir surface fluctuates throughout the upper one-third of the height of the dam. In this part of the structure the reinforced concrete deck slabs are about 16 in. thick. The deck concrete is of 1 : 2 : 4 proportion, the minimum thickness being 12 in.

In the main the foregoing information regarding the Eugenia Falls Dam was furnished by the Chief Engineer of the Commission, F. A. Gaby, M. Am. Soc. C. E. Mr. Gaby has further stated that recent inspection showed that the lower faces of the deck slabs have not disintegrated. A minor amount of flaking is said to be in evidence in the upper part of the up-stream face of the deck at some of the construction joints, this being attributed to the fact that the upper parts of many of the deck slabs were poured during the unfavorable temperatures of December. From the performance of this structure Mr. Gaby infers that concrete with proper proportioning and good mixing, so as to result in a dense product, will successfully withstand rigorous conditions of cold.

Enclosed Hollow Concrete Dams

One need not be surprised that there are various instances of hollow concrete dams (generally of the Ambursen type) which are completely enclosed along the down-stream faces of the buttresses and which have suffered no disintegration of concrete. In general, the enclosure results from the use of a complete spillway apron. An example of such structures, which has been visited in person by the speaker, is the Warrior Ridge Dam of the Penn Central Light and Power Company, on the Frankstown Branch of the Juniata River in Penn-

* *Engineering News*, March 9, 1911, pp. 288-291.

sylvania. This structure, about 30 ft. high and about 450 ft. long, is entirely of spillway section. It was constructed in 1906, thus having about 20 years service to its credit. The speaker's earlier observation as to absence of disintegration has been confirmed more recently by several other engineers.

Other Cases of Disintegration

To mention several other instructive cases where disintegration of concrete in dams has occurred, the first is an intake dam,* on Bishop Creek, in California, likewise on the eastern slope of the Sierra Nevadas, which suffered some disintegration on the down-stream face of the relatively thin section of the dam. This disintegration is reported to have been stopped by an earth back-fill against the down-stream face, thus preventing extreme temperature variations at the surface of the concrete.

Stony River Dam, West Virginia.—A case with which the speaker has had considerable personal contact is that of the hollow, reinforced concrete dam of the Ambursen type, on Stony River in West Virginia.† This dam is situated in the northern part of the State at an altitude 3 400 ft. above sea level, and is subject to severe freezing weather. It was constructed in 1912-13, failed in part in January, 1914, by the undermining of a too shallow cut-off wall, and was reconstructed in 1914-15, the reconstruction being under the supervision of the speaker.

In the concrete of both the original work and the reconstruction local sandstone was utilized for the coarse aggregate and likewise, by crushing and rolling, for the sand. In both cases the concrete was placed wet, one might say "slushy". The deck slabs were of 1 : 2 : 4 concrete. In no respect had the failure of the dam been due to the quality of the concrete; in fact, the good appearance of the original concrete in the spring of 1914 led to the decision to continue the use of local aggregates. The only excuse for the wet concrete lies in the fact that at that time such was the generally accepted practice.

As part of the reconstruction certain structural modifications were made. That part of the dam which had failed had been of open bulkhead section, but this was replaced by means of a second spillway, which, like the original spillway, has a completely enclosing apron on the down-stream side. Furthermore, in order to prevent freezing of the foundation drainage system, installed throughout the entire dam as part of the reconstruction, a concrete housing was built in all the previously open bulkhead bays, except only the bays of lesser height near the ends of the dam.‡ This housing consists of a curtain-wall of concrete, 12 in. thick, extending for about two-thirds of the height of the dam, together with a roof, 7 in. thick, extending horizontally from the top of the curtain-wall up stream to a junction with the deck.

The water-level fluctuates considerably. There is no fixed regimen which applies one winter after another.

During the first six years of the life of the original concrete, that is, until 1919, practically no evidence of disintegration was discernible. An inspection

* See p. 724.

† *Transactions*, Am. Soc. C. E., Vol. LXXXI (1917), pp. 907-1100.

‡ *Loc. cit.*, p. 955, Plate XII.

in the autumn of 1919, however, revealed some spalling of concrete on the upstream face of one of the original deck slabs near the center of the dam. It is presumed that the spalling originated during the severe winter of 1917-18, for which period a minimum temperature at the dam of 36° below zero Fahr., was reported. At the time of this inspection the spalling extended to a depth of about 5 in., the total thickness of the deck slab at this point being about 14 in. The spalling extended across the entire width of the deck slab (about 13 ft.); this fact, together with the further fact that this slab was the only one which had spalled, indicated that the disintegration may have been due to improper treatment of the concrete in that particular area. In 1921 the disintegrated slab was patched by superimposing a reinforced concrete slab. However, water penetrated between the original and superimposed slabs and the disintegration of the original slab continued, until finally the concrete crumbled and spalled on the lower or down-stream face of the slab in the same region, exposing the reinforcing steel.

In the meantime the two adjacent deck slabs were showing an increasing seepage through the concrete, thus casting doubt on the earlier indication that the slab first showing disintegration had been subject to an isolated instance of faulty workmanship. It is likely, however, that this particular part of the original deck was made of concrete in which, as compared with the remainder of the work, there was aggravated some error in making the concrete, as, for instance, excessive water-cement ratio or improper curing. The slabs in point were undoubtedly cast at a time when there was no freezing and possibly even during hot weather. Further repair work was done during 1924.

The area affected comprises only about one-fourth of 1% of the total deck area of the dam. It is important to note that there is no record of any disintegration below the roof of the housing (which applies to about three-fifths of the bulkhead sections of the dam), and, similarly, that there appears to be no disintegration whatsoever within either the old or the new spillway, and, therefore, completely enclosed, sections of the structure.

The fact that in the new spillway section there has been no disintegration, whether of deck, apron, or buttresses, is the more noteworthy because there has been considerable disintegration in the new spillway mat or channel flooring and also in the concrete placed during the reconstruction to reinforce the footings in that part of the dam which had not failed. This disintegration of the newer concrete was most marked on horizontal, or only slightly inclined, surfaces. The newer concrete which has suffered disintegration was undoubtedly made with too much water and too little cement, especially considering the quality of the aggregate used, and much of the concrete was placed during the winter. However, as compared with the new concrete which disintegrated, the concrete of the new spillway similarly contained too much water; the cement content for the spillway was greater only in the deck and apron ($1 : 2\frac{1}{4} : 3\frac{3}{4}$), but not in the buttresses, which, like the spillway channel mat, were of $1 : 2\frac{3}{4} : 4\frac{3}{4}$ mix.

The new deck concrete is not superior to that of the original decks. The former are somewhat thicker at the same elevations, but the speaker believes that it is primarily because of the complete enclosure that the new decks

withstood successfully the severe winter of 1917-18 and appear still to be in excellent condition.

In considering possible causes of the disintegration of the small area of deck slab in the original part of the dam, the question arises whether the difficulty may not have focused at and been due to the ice sheet covering the reservoir in winter. The water surface of the reservoir may actually have been at or slightly above the disintegrated area during the winter of 1917-18; moreover, the fact that the disintegration was first noticeable on the up-stream surface implies that there may have been some plucking action on the part of the ice, thus causing the observed spalling. However, other facts indicate that the ice sheet is not primarily responsible, but rather that it may have accentuated and made obvious a disintegration which had an earlier and more direct cause, namely, percolation of reservoir water through the deck slab and consequent freezing of the slab while in a saturated condition and unprotected on the down-stream side. One fact bearing on this matter is that the water level is by no means fixed seasonably; another is the experience in the case of the Gem Lake Dam where the disintegration extended for many feet below the winter water level of the reservoir.

Limitation of Disintegration to Unenclosed Dams.—The speaker is familiar with or has reports on disintegration of concrete in various other hollow concrete dams, both of the multiple-arch and reinforced concrete deck-slab types. However, persistent inquiry on his part has not revealed to date a single instance where disintegration of concrete has occurred in the decks of hollow concrete dams in which the down-stream faces of the decks are protected against severe freezing temperatures. He would not have been surprised to learn of some cases where obviously poor concrete had disintegrated even under such protected conditions, for, at best, a relatively thin slab subject to percolation from reservoir water is functioning under severe handicaps. The apparently complete absence of disintegration in enclosed parts of hollow concrete dams thus seems all the more remarkable.

Time and space do not warrant consideration of the disintegration of concrete which has taken place in altogether too many solid concrete dams, but it is worthy of note that such disintegration has occurred primarily in regions where there is severe freezing and in parts of dams which are fully exposed to the prevailing atmospheric conditions. Incidentally, the disintegration which has occurred in such dams appears to be greater as the surfaces approximate the horizontal.

Tentative Conclusion

In the light of the foregoing considerations, the speaker has reached the tentative conclusion that hollow concrete dams may be constructed and relied on to be relatively permanent, provided:

1.—The design is good and the proportions of the members liberal, especially as regards thickness of concrete protecting any reinforcing steel.

2.—The concrete is made of proper materials and in a proper manner, in accordance with present knowledge of the art. This involves capable, conscientious, rigid, and authoritative inspection.

3.—The dams are enclosed by means of diaphragms or heat-insulating walls located at or near the down-stream faces of the buttresses.

This tentative conclusion has been reached with full recognition of the fact that hollow concrete structures of necessity can tolerate disintegration to a less extent than solid concrete dams. The point is that disintegration is believed to be avoidable.

The speaker is sufficiently optimistic to believe that hollow concrete dams can be built in freezing climates successfully even without the enclosure. However, in view of the present status of the art of concrete construction and the contingencies which at best enter into any concrete work, he believes it is not conservative to rely entirely on obtaining the proper quality of concrete.

The most important quality to be attained in the deck concrete is, of course, water-tightness and this, in turn, is directly dependent on the density of the concrete itself. Without presuming to have any final knowledge on the point, the speaker doubts the practicability of obtaining in dams reliably water-tight concrete decks by means of surface or membrane coverings. Acknowledging that, in general, such coverings must be of some benefit, he prefers to place his main reliance on properly attained density of the concrete itself.

As to the character of the recommended enclosure, it should be noted that the form of the enclosure in the case of the Stony River Dam was governed by a different consideration. If this point of protecting the entire down-stream surface of the decks had been in mind, the enclosure would undoubtedly have been carried to the full height of the dam. A fact of importance developed in the functioning of the Stony River Dam is that within the enclosure the temperature does not fall materially below the freezing point. For instance, during the winter of 1915-16, the lowest temperature within the enclosed part of the dam was + 26° Fahr., whereas the lowest outdoor temperature was — 12° Fahr. Under these conditions no serious ice formation took place within the enclosure. Evidently, the radiation of heat from the reservoir water and from the foundation material into the enclosed space to a large extent offsets the radiation of heat through the enclosing diaphragm from the enclosed space into the outside air.

The down-stream insulating wall may be of concrete, either single or, better still, double; in the latter case, it affords an insulating air space within the wall. Hollow tile also seems appropriate for the purpose. The tile might be coated with stucco or gunite if a more pleasing appearance is desired. Incidentally, such a diaphragm, especially if of concrete, serves as a brace between buttresses.

The water-works reservoir dam, at Coatesville, Pa., of the Ambursen type and constructed under the supervision of Alexander Potter, Assoc. M. Am. Soc. C. E., in 1916-17, is understood to have its non-spilling concrete sections enclosed by an approximately vertical diaphragm of No. 28, four-rib "Hyrib" (a form of metal lathing), covered by a 1-in. thickness of plaster. However, it is further understood that such an enclosure is solely for architectural effect. The speaker also notes with interest Mr. Reed's statement

that one of the more recent Norwegian dams, the so-called Fjergeng Dam, is enclosed by an insulating wall on the down-stream side.

Miscellaneous

The speaker will await with much interest the result of the long time test by Nature as to the quality of the concrete used in the Gem Lake reconstruction work, especially in view of the somewhat low cement content. It would be of interest to know in what direction the diagonal cracks extend, that are mentioned by the authors as having occurred near the up-stream toes of three of the buttresses. It appears not unlikely that these cracks are of the same nature as those mentioned by Mr. Lippincott.

Charles W. Comstock,* M. Am. Soc. C. E.—The dominant note in the preceding discussion seems to be one of condemnation of the concrete used in the original construction. From this opinion the speaker dissents.

Records of concrete tests made during construction are not at hand, but the speaker has had access to them and has studied them carefully. To the best of his recollection compression tests on 6 by 12-in. cylinders at 28 days gave upward of 1 900 lb. per sq. in. Generally this would be regarded as satisfactory.

The speaker made an examination of Gem Lake and Agnew Lake Dams in May, 1924. The exposed portions of both dams, arches and buttresses, were carefully gone over with pick and hammer. Holes were drilled or dug at various places where indications were unsatisfactory. Except for the belt, about 30 ft. wide, of the arches of Gem Lake Dam, which has been described in the paper, the concrete was satisfactory in appearance and perfectly sound, ringing clearly when struck with a hammer. The buttresses at Gem Lake were in perfect condition. There was no spalling or other evidence of deterioration. Agnew Lake Dam was apparently in perfect condition throughout.

The speaker was not connected with the original construction of these dams and has no personal reason for defending the methods or materials used, but all the evidence indicates that the work done and the results obtained were as good as possible with the materials available.

Mr. Flinn has suggested that concrete materials should be selected with greater care than is usually bestowed upon them, that they should be carefully analyzed and scientifically proportioned. While the soundness of this suggestion will not be questioned, and it is certain that the best results cannot otherwise be obtained, it should be remembered that the constructor is nearly always limited by considerations of cost to the sand and coarse aggregate afforded by the surrounding territory. Cement is purchased under standard specifications with which all established brands comply. Defective concrete is rarely due to poor cement, although sometimes to improper manipulation.

In the speaker's opinion unsatisfactory concrete results more often from poor sand than from any other one cause, but in this material the constructor frequently has little or no choice. The alternative is to use the best that is available and be content with concrete of quality inferior to the ideal.

---

* Engr., Dwight P. Robinson & Co., Inc., New York, N. Y.

At the time of the reinforcement of Gem Lake Dam the sandpits used in the original construction were entirely submerged and inaccessible. The nearest natural sand would have had to be hauled 16 miles and then drawn up the inclines and barged across Agnew Lake, as was done with cement and lumber. The cost was prohibitive. It was necessary to grind the country rock to obtain sand. Whether the new concrete will be superior to the old remains to be seen.

A word as to Agnew Lake Dam—it is about 550 ft. lower than Gem Lake and was built to afford storage for one or two seasons prior to the completion of Gem Lake Dam. Since the completion of the upper dam water stands almost constantly at spillway level in Agnew Lake, thus protecting the water face against freezing on that side. Agnew Lake Dam is only a little more than 30 ft. high, and snowdrifts pile up to its full height on the lower side every winter. This affords ample protection against the freezing which has damaged a part of the Gem Lake structure, and accounts for the present sound condition of the lower dam.

After a careful study of both these dams the speaker was unable to find any other explanation of the peculiar nature and location of the damage than that given in the paper. He does not believe that the facts square with any assumption of poor concrete in the original construction. Whether it would have been better to have chosen an entirely different type of dam in the first place is another question.

George W. Howson,* Assoc. M. Am. Soc. C. E. (by letter).—This very frank discussion of the failure of the concrete in the arches of the Gem Lake Dam is extremely interesting to those engaged in the design and construction of dams, and carries a warning to those building thin exposed walls subject to water pressure. Many theories may be advanced as to the cause of the failure, but all are without conclusive proof. The most logical conclusions have been reached by the authors that moisture found its way into the concrete and there froze, causing disintegration. They rightfully conclude that field construction conditions make extremely difficult, if not impossible, a concrete absolutely impervious to the slightest penetration of moisture. It is gratifying to note that they conclude that the rock-fill type has many advantages over other types of dams in such a locality as Gem Lake. The writer believes that the virtues of the rock-fill dam extend further than to localities such as Gem Lake. It adapts itself to certain foundations, such as loose rock or cemented gravel in stream beds, requiring a minimum of excavation compared with masonry dams. There is a tendency toward the popularity of the rock-fill dam, probably due to the increasing familiarity of engineers with it. The writer has knowledge of five large proposed dams, all of the rock-fill type.

The rock-fill dam is not susceptible to such a refined degree of analysis as the multiple-arch, and owing to the very nature of the structure it is not necessary that it should be. The design is largely a matter of experience and not of refined computation.

* Res. Engr., Dix River Dam Project, Burgin, Ky.

Recently, the writer has been in charge of the construction of the super-rock-fill dam on the Dix River in Kentucky, designed by L. F. Harza, M. Am. Soc. C. E. This dam is 275 ft. high above the stream bed and 296 ft. above the foundation excavations. It contains 1 800 000 cu. yd. of material and is by far the master effort yet attempted in this type of construction.

When properly designed the rock-fill dam has, for a water-tight skin spread over the exposed up-stream face, a layer of reinforced concrete which, in the larger dams, generally varies from a maximum of 2 ft. to a minimum of 6 in. in thickness. In this respect the rock-fill type has something in common with the multiple-arch; both rely on a thin slab of concrete for water-tightness. In case of the rock-fill dam the concrete slab is protected from the elements on the lower side by the mass of the rock-fill over which it is spread and on which it relies for support. In the multiple-arch dam the thin arches are exposed on the lower side to the elements, and it is believed to be this exposure at Gem Lake that caused the failure.

The large rock-fill dam must have a concrete water-skin of a quality equal to, if not better than, the arches of a concrete structure. It must be as nearly impervious as possible and, in addition, be able to develop great strength to meet indeterminate stresses due to movements in the rock-fill itself. By proper construction of the body of the dam, movements of the fill may be partly controlled and reduced in amount, but nevertheless they are present in a greater or less degree, depending on the intelligence, guided by experience, used in the supervision of the construction of the fill. Once the apron of concrete is poured against the fill it must conform to the movements or take stresses sufficient to overcome them.

No concrete apron spread over the face of a large rock-fill dam would be able to resist major movements of the dam, nor is it ever intended that it should in a well-designed apron; but the apron may be so designed and so constructed that it can overcome tendencies to small local movements. This is a matter of the fine combination of proper design and good supervision so necessary in dam construction.

FRED O. DOLSON,* AND WALTER L. HUBER,† MEMBERS, AM. SOC. C. E. (by letter).—The writers' conclusion that a type of dam other than the multiple arch should be selected for a site such as that at Gem Lake is well demonstrated by the great diversity of opinion, as to causes of deterioration and as to remedies, displayed in the discussions. The wide interest shown by this full discussion is, to them, a source of satisfaction.

The positiveness and the wide diversity of opinion regarding the quality of concrete in the original structure would be amusing if it were not to some extent a reflection upon the profession. It is interesting to note that criticism of materials and workmanship of the original structure is offered by those who have not made a personal examination, while others, as, for instance, Mr. Comstock, who made a careful inspection of the structure previous to its repair, defend both and state that the evidence indicates that the work

* Vice-Pres. and Asst. Gen. Mgr., Southern Sierras Power Company, Riverside, Calif.
† Cons. Engr., San Francisco, Calif.

done and the results were as good as could be obtained with the materials available. Many points brought out in the discussion are worthy of further consideration.

Mr. Jorgensen contributes some interesting notes from the laboratory which made the analyses and tests of materials used in the original construction, as well as some interesting facts relating to that construction. He refers to some similar dams in Northern Sweden where low temperatures are encountered, and states that no damage has occurred in two years, although he admits that these dams are partly back-filled with earth as a protection against low temperatures.

In personal correspondence Mr. Jorgensen states that for each of the dams the back-fill behind the arch section covers that part which remains below the water level during cold weather. The writers are in entire accord with his conclusion that under severe freezing conditions it can hardly be expected that a plaster face applied to a thin concrete section will have a long life.

Mr. Jewett has offered some of the results of the many tests he made for The Nevada California Power Company in an effort to find a coating which would afford a water-tight face and, at the same time, would offer some degree of permanence. The defects of many so-called "water-proofing" compounds are intimated if not actually expressed. It will be noted that Mr. Jewett has, wisely in the writers' opinion, avoided the use of any trade names.

As an example of incorrect conclusions, Mr. Wheeler and Mr. Lane attribute the disintegration of the concrete to the presence of limestone and limestone dust. It is interesting to note that, in the lower part of the dam where the limestone (mentioned by Mr. Jorgensen as coming from the outlet tunnel) was used, no disintegration has occurred, whereas in that part of the dam which has disintegrated this limestone was not used.

Mr. Turner mentions certain concrete dams, much thinner than the Gem Lake Dam, and exposed at times to temperatures of 50° Fahr. below zero, but he does not state where these structures are located and at what season the water stored behind them is drawn down; consequently, the writers have been unable to make a comparison.

Mr. Wiggin credits the writers with calling attention for the first time in a pointed way to the fact that the immersed side of a thin exposed wall of concrete is in the same danger from the formation of ice crystals in its pores, under the influence of cold coming through from the dry side of the structure, as the side not immersed in a thick, leaky wall.

The writers note Mr. Howell's agreement with their conclusions and his reference to another dam of thin section of the flat-slab type which is deteriorating in the same manner.

Mr. Waugh, who is thoroughly familiar with all conditions at Gem Lake Dam, having assisted in its original construction as well as having had charge of its repair, attributes the primary cause of the disintegration to the failure of the gunite coating to prevent moisture from getting in back of the top

skin. His conclusions are substantially in accord with those of the writers, that the slightest penetration of water under such climatic conditions will be followed by deterioration. In the paper doubt was expressed as to whether, under conditions imposed for construction at such sites, impervious concrete can be obtained under present-day conditions. After several seasons of hard-earned experience in carrying the responsibility of construction in this difficult location, Mr. Waugh is even more positive that "it is inconceivable that any concrete will prevent the penetration of moisture."

Mr. Flinn's suggestion that Engineering Foundation should collect data concerning the behavior of other thin section dams is a valuable one, providing such data are complete and include temperature records, raising and lowering of water surfaces, etc. The writers feel that they have not overemphasized one example of deterioration. They have placed a notable example before the profession as completely as they have been able to present it and, through the discussion which has followed, as well as from other sources, have learned that this is by no means an isolated instance. In their opinion the serious tendency has too often been to observe complete silence in the case of sad experiences. Such experience is a rightful heritage of the Engineering Profession. Examples of similar structures that have stood (and the writers do not believe such success will be found in similar locations) will not afford a sense of security to the designer contemplating a new structure of this type to withstand similar conditions. To use the terse expression of another discussor, "engineering is not a matter of majorities".

Senator Luiggi gives some interesting observations on the Gleno Dam, a multiple-arch dam in Italy, which failed but not from causes such as the deterioration at Gem Lake Dam. The writers are glad to note his concurrence in their opinion that for such a locality as that at Gem Dam a rock-fill dam has many advantages over other types. Senator Luiggi questions the use of preparations such as "Ironite", or neat cement applied with a cement gun, in which view the writers concur. The effectiveness of these coatings is impaired by the expansion and contraction of the arches of the dam. He suggests methods of water-proofing the up-stream face of the dam; but since the methods suggested would necessitate the loss of at least one season's storage the cost is thus rendered greater than that of the method chosen.

The contribution of Mr. Merriman is, in the opinion of the writers, one of the most valuable and constructive of all those submitted because he points out the difficulty, not only of making good concrete up to the point of placing it, but the danger in not properly caring for concrete while it is curing. Neglect of concrete during curing occurs in the great majority of cases. Mr. Merriman is to be commended for bringing this out so pointedly.

Mr. O'Shaughnessy makes inquiry concerning the resultant losses sustained by the failure of the dam to function during certain seasons. During 1923, when an effort was made to water-proof the face of the structure, the loss was 10 000 acre-ft. of storage—a heavy loss when it is realized that at this locality this quantity amounts to approximately 12 000 000 potential kw-hr. The probability of having to face a similar, or even greater, loss in 1924 was

one of the deciding factors in favor of the method of repair chosen, which was carried out entirely from the down-stream side with no loss of storage. Mr. O'Shaughnessy states that in an arch dam it is necessary to have concrete of such density that it will be water-proof. In the opinion of the writers, concrete which will not absorb moisture to any degree whatever does not exist. Therefore, for climatic and operating conditions, such as obtain at Gem Lake Dam, it is absolutely necessary that the impervious surface be provided next to the water, as required by the principles of Mr. George L. Dillman which were referred to by Mr. O'Shaughnessy. If this face is provided and is permanent, it should be immaterial whether the concrete back of it is porous, so long as this concrete is able to withstand the stresses imposed upon it as a structural element of the dam. The writers are glad to note that Mr. O'Shaughnessy, with his extensive experience, commends a rock-fill type for a location such as that at Gem Lake Dam. It is also interesting to note that Mr. O'Shaughnessy plans ultimately to replace the buttressed arch dam at Lake Eleanor with one of a rock-fill type.

Mr. Lippincott very clearly expresses an idea, which the writers have endeavored to make plain, in his statement:

"Although a thin shell of concrete may be made water-tight against percolation, it is not possible by any process known to the writer to prevent it from absorbing water when in contact with it."

Observations of diagonal cracks in the buttresses of several multiple-arch dams have been made by the writers and they are in entire accord with Mr. Lippincott's views that these buttresses should be reinforced. These diagonal cracks, although not an important consideration in Gem Lake Dam, did exist near the up-stream toes of three of the buttresses. They are described and comments are made on their prevalence in other multiple-arch dams under "History of Operation" (page 716), in the writers' paper.

Mr. Reed makes inquiry concerning the conditions at Agnew Lake Dam, a smaller but similar multiple-arch dam on the same stream approximately 550 ft. lower in elevation. The concrete in Agnew Lake Dam has not disintegrated, but a small amount of leakage has developed. The gunite surface was removed in 1925 and various types of water-proofing compounds are now being tried on the up-stream face. In the opinion of the writers, deterioration of the concrete in Agnew Lake Dam has not occurred because some protection from extremely low temperatures is afforded by the snow with which the entire down-stream face is usually covered before the extreme cold weather occurs. In fact, the arches are banked full of snow at such times. The protection by such banking is apparent from the fact that a valve enclosed in a light board shaft does not freeze. Mr. Reed cites instances of multiple-arch and flat-deck dams that have been successful in Norway and Sweden, but indicates that protection against low temperatures has been provided. In the opinion of the writers such protection is essential.

Mr. Jakobsen opens his discussion with a statement that it would be hazardous in the extreme to conclude anything from the behavior of a single structure and more especially since other similar structures, subject to equally

severe conditions, have shown no sign of deterioration. His references to such structures are very meager indeed. It would be interesting to know the exact location of each and to have exact climatic and operating data for each. Mr. Jakobsen apparently has missed the statement in the "Introduction" (page 714) to the writers' paper to the effect that a large amount of mathematical discussion concerning multiple-arch dams had already been presented, and that it was not intended to include any addition to such material. The paper was a discussion of a failure and a method of repair, not of the theory of design. He can rest assured, however, that thorough analyses of the new section and of its effect on the remaining original structure were made, not only by the engineers of The Nevada California Power Company, but by the several consulting engineers who were employed and that no important considerations were left to off-hand assumption as he seems to infer.

Mr. Oesterblom seems to have missed some of the salient points of the paper. It is easy to understand why the middle belt of the arches was affected and why the section at the bottom, as well as at the top, was little affected. The up-stream faces of the lower parts of the arches are generally submerged to considerable depth in water, which insures somewhat warmer temperature. At the same time the backs of these arches are protected from extreme low temperature by the early snows drifting against them, thus forming a blanket; also, the arches themselves are much thicker at this point, thus affording less opportunity for the extreme cold to chill the material completely. These conditions, combined with the fact that the upper sections, from which water is always drawn before the advent of cold weather, do not show deterioration, seem to afford ample proof that frost action is the controlling cause.

Mr. Collier offers a conjecture on what results would have been obtained had a thicker coating of gunite with reinforcing been applied. He states, in closing, that with a thickness of approximately 2 in. of reinforced gunite, experience has shown that positive water-proof conditions will be obtained. It would be interesting to know the number of years during which such conditions have obtained on any structure and what conditions of expansion and contraction, or of deflection, occur in the operation of the structure. The writers believe that a gunite face of these specifications would have prevented percolation of water at first, but that over a period of years the gunite would have absorbed water and would have disintegrated to such an extent that water would have been admitted to the concrete back of it, unless it was replaced before this occurred.

With much of the discussion of Mr. Noetzli the writers disagree entirely. Mr. Noetzli refers to the Lake Eleanor Dam as being an entirely successful structure, but apparently he has not noted that Mr. O'Shaughnessy, from his discussion, plans ultimately to replace this structure with a rock-fill dam. He refers to the Bear Valley Dam as being a similar structure with similar climatic conditions. At the Bear Valley Dam the reservoir is not regulated for hydro-electric power development and is ordinarily not drawn down during the winter. At this location temperatures do not range as low as at Gem Lake, nor do long sustained extreme cold spells occur. Climatic conditions are not

comparable. After referring to the adopted method of repair as being as radical and expensive as could be devised, he launches off with confidence into advocacy of a method that was considered and discarded by the several engineers who studied this problem for the owners. His method is not believed to be feasible, even if considered only with relation to this single structure. However, Mr. Noetzli has completely missed an important practical point. Gem Lake Reservoir is now an important and necessary part of a great operating hydro-electric system. Any method of repairing Gem Lake Dam that would render the reservoir useless for a storage season, or even a part of such season, must prove expensive, due to loss of revenue; Mr. Noetzli's proposed method would cause such a loss. The method adopted avoided this great economic loss and thus it has a large differential in its favor. Mr. Noetzli does not consider that a loose rock-fill, which is relatively porous, will materially protect a concrete core wall or a concrete face slab against low temperatures. The writers know the facts to be otherwise. Proof can be secured by taking temperatures in tunnels through rock-fill dams where it will be found that at a distance of about 60 ft. in from the tunnel portal water will not freeze. For example, Mr. Dolson had occasion to construct a tunnel 157 ft. in length through the Skagway Dam near Victor, Colo.; later, he used this tunnel for the storage of foodstuffs and found that 60 ft. in from the tunnel portal no freezing occurred.

The several examples of hollow concrete dams described by Mr. Scheidenhelm are interesting, but those particular structures which are enclosed by a deck on the down-stream face are not comparable.

The writers wish to express their appreciation of the very clear statement from Mr. Galloway, interpreting the lessons from Gem Lake Dam which they have offered to the profession. He has most clearly and concisely pointed out the value which may be gained from a proper interpretation of an engineering failure.

A dam of the thin multiple-arch type, if it is to resist the conditions existing at sites such as at Gem Lake, must depend on a permanently impervious face; but, under present-day conditions, the writers know of no practical means by which such permanent imperviousness can be obtained nor has the discussion disclosed one. They, therefore, adhere to the opinion already expressed that for this or similar locations a dam of the rock-fill type has many advantages over other types.

In closing, the writers express their appreciation to the officers of The Nevada California Power Company for their courtesy and their frankness in granting permission to publish a full account of the investigation and repair of this structure. It has been a source of satisfaction to note expressions of appreciation of the Company's attitude from many of those who have contributed to the discussion.

Excess Condemnation in Massachusetts.
By Frederic H. Fay, M. Am. Soc. C. E. 816

With Discussion by Messrs. Horace H. Sears, Frank O. Whitney, Andrew Wright Crawford, Harold M. Lewis, and M. W. Weir.

* Presented at the meeting of the City Planning Division, New York, N. Y., January 22, 1925.

THE PRESENT STATUS OF EXCESS CONDEMNATION IN THE UNITED STATES

By Frank B. Williams,* Esq.

Excess condemnation is the technical remedy for a legal technicality, and being the outgrowth of bad logic, is difficult to explain clearly. It has been defined as the taking by eminent domain (and, therefore, without the consent of the owner) of more land than is needed for a public improvement. The practical man realizes that the development of the land outside the lines of the given improvement, so as to harmonize with the improvement within them, is essential to the attainment of the maximum usefulness of that improvement. In short, he knows that the outside land—not in fact "excess"—is needed for the improvement. This, the judges in the United States, apparently have not been able to realize. The result is that the Courts in this country have held as unconstitutional several statutes of excess condemnation, and in a few States constitutional amendments have been passed authorizing it.

There are two main purposes for which excess condemnation, as it may for convenience be called, can be used with advantage in public enterprises, as follows:

1.—It may be used for the profit to be obtained by the re-sale of the "excess" land.

2.—It may be used for the purpose of controlling the development of this "excess" land so that it and the main improvement may best be utilized each in connection with the other and both render the greatest service to the community.

A few illustrations may not be out of place. Excess condemnation is usually advocated either for the laying out of a new business street, or the widening of an existing one, in a neighborhood in the center of the city where the present developments are unsuitable or unsanitary and of low value; or for the construction of a thoroughfare in the outlying part of the town where the land is relatively unimproved. In these cases one of three results may occur, as follows:

First.—The neighboring land may be increased in value, in which case it would be good business, if there is sufficient capital and the matter can be handled with skill, to take this land and sell it to pay in part for the street. Failure to follow this course increases the cost of this and similar enterprises, to the public loss. In this age of keen competition no private business could long neglect such incidental economies and escape bankruptcy.

Second.—There may be parts or remnants of lots on one or both sides of the new street which are too small for independent development and which also shut off land from it and, therefore, from proper improvement. If the uniting of the remnant and the land in the rear is left to private initiative, considerable time may elapse during which proper buildings will

* Attorney-at-Law, New York, N. Y.

not be erected on the street, or cheap ones will be constructed, with a loss, in either case, to the city in taxable values and to the community in the lessened economic service of the land and the street. Often the tone of a street is in this way permanently lowered, the ugly temporary structures giving it a character which it never afterward outgrows.

Third.—Even if the contiguous land is not cut into remnants, the use to which it is put may lessen the value of the thoroughfare. A boulevard with ugly houses along it, is not the beautiful boulevard for which the city has spent its money so freely. A view which the boulevard was planned to exhibit may be cut off by a row of houses, whereas the erection of detached structures, with ample space between, would have left it open and the land would have sold as well if not better. A much needed industrial street with the adjoining land cut into small irregular lots is not capable of use for enterprises requiring large sites. The desired conditions may often be obtained by the proper subdivision and planning of the contiguous land, and its re-sale for private use without any legal restriction on it, because conditions suited to the street having once been created may be relied on, as a rule, to continue. Of course, legal restrictions in favor of the city may be placed on the property if deemed wise; and, when suitable, such restrictions often enhance the value of the property affected, as real estate dealers and owners have found by experience.

The thoroughfare is not the only improvement with which excess condemnation may be used; indeed it may be used as a part of most public works. Thus, a new city hall properly located and constructed will cause neighboring land values to increase; and the public by proper business management could secure the profit which its enterprise has created, condemning and re-selling the land for that purpose. A beautifully designed city hall is not the structure of beauty it should be unless it has an appropriate setting. Often the cheapest and indeed the only feasible way of obtaining some measure of setting is by the control of the architecture of near-by buildings. In similar ways the construction of parks may be made a source of income to offset in part their cost, their beauty and utility being increased by the control of the neighborhood which only excess condemnation will give.

Excess condemnation, and the various expressions used for it in foreign countries, are terms of modern origin; indeed the concept itself is the product of a legalistic age. Excess condemnation in fact, however, has been practiced very generally throughout the past. A monarch, not hampered by the division of powers, has found it quite natural to take abundant land for an enterprise he had undertaken, carrying it out as seems wise, and selling any surplus or giving it away with any necessary conditions attached to insure the completeness of the work. All will remember the humble citizen in one of Molière's plays, who, suddenly and enormously enriched, took a Master of Philosophy as an instructor, only to discover to his amazement that for forty years he had been speaking prose without knowing it. Thus, the administrators of former ages used excess condemnation with entire ease before, technically, such a thing existed. It is to excess condemnation in this sense that we owe the Place des Vosges in Paris, France, and many other beautiful and useful squares and streets in Europe.

Excess condemnation in the modern meaning of the expression seems to be French in origin, and is to be found in most foreign countries. It has been extensively practiced in England, usually for the profit that could be recouped to pay in part for the main improvement. It was provided for and considerably used in the State of New York under a statute enacted in 1812, but was held to be unconstitutional by the New York Courts in 1834, and virtually ceased to be practiced until revived by statutes in Massachusetts and Ohio in 1904 and subsequently in other States. These statutes were so criticized by the Courts that little use was made of them and constitutional amendments for the purpose were passed, first in Massachusetts (1911), and then in Ohio (1912), Wisconsin (1912), New York (1913), and Rhode Island (1916).

Whatever doubt there may have been with regard to the validity of the statutes of excess condemnation, under the State Constitutions as interpreted by the State Courts, there can be no doubt with regard to the validity of the constitutional amendments, which can be challenged only on the ground that they are contrary to the Constitution of the United States as construed by the Supreme Court. This may be asserted with confidence in spite of the fact that no case involving excess condemnation has ever come before the Supreme Court. There is an impression that the State Courts are often more narrow and technical than the United States Supreme Court. Be that as it may, this is not the reason for the confidence so generally felt by students of the subject. Land taken by excess condemnation, like land appropriated by condemnation proper, is acquired by eminent domain, which can be invoked only for a public purpose. In deciding what is a public purpose the Courts are guided both by history, which is past usage, and by current custom, which is history in the making. Local conditions also have great influence. In a country as large as the United States, past history, present opinion and custom, existing physical conditions, and surrounding circumstances, differ greatly in its widely separated sections. It cannot be assumed, therefore, that there is any one standard that can be set for the entire country, in accordance with which such questions can be decided; the locality must be studied and the question settled in the light of what it reveals. For instance, the Supreme Court has held that irrigation is a public purpose in a dry State like California, whereas it might not be so in the Eastern States. In so deciding, the United States Supreme Court followed the decision of the Supreme Court of California. The Supreme Court gives great weight in the decision of such matters to State laws and constitutional provisions as interpreted by the highest Court of the State in question, considering them to be most persuasive evidence of local conditions; so much so that in no case has the United States Court held invalid, under the National Constitution, a taking of property by eminent domain under a State law upheld by the highest Court of that State.

Excess condemnation has been utilized with success abroad, especially in England. In this country, it has been used comparatively little, in spite of the fact that the need of it, in numberless instances, is clear.

One of the reasons excess condemnation is not more used in the United States is that in many instances the procedure provided for it is not practical. City planners, in various parts of the country, although fully realizing the

advantages of excess condemnation in an enterprise, cannot see any way under existing laws to make it a success. A study of the laws of excess condemnation throughout the country, in consultation with city attorneys and engineers, would be a great service to the cause of city planning.

A second reason excess condemnation is so little resorted to in this country is the undue conservatism of city attorneys. They have an excessive reluctance to apply methods that are not already in general use, and thereby sacrifice the progress that can come only from improvement in method. The writer is also at times tempted to think that this comes in part from an unwillingness to do the work involved in any change in their usual routine.

A third reason excess condemnation is so little used in the solution of problems urgently calling for it, is the debt limit and the financial condition of cities. To take land several times in excess of that needed for the work within the narrow lines of the principal improvement calls for the outlay of many times the capital required for the main improvement; and, with many public enterprises urgently calling for funds, and a rigid debt limit almost if not quite reached, it seems impossible to get the necessary capital for the many years during which it will be tied up. A new thoroughfare, or similar undertaking, can be begun with a small expenditure, the cost being assessed against those especially benefited, to be paid by them in due course. In addition, there is the conservatism of city administrators who find it so much easier to do the work in the old way, even if thereby many of its advantages are sacrificed. There is also the unwillingness still existing among the mass of the voters, to the giving of authority to officials to enter into what is, in some of its aspects, a business transaction involving some speculative elements and the possibility of favoritism and corruption.
